The Office of Policy Development and Research
U.S. Department of Housing and Urban Development

Rand
SANTA MONICA, CA 90406
The Housing Assistance Supply Experiment (HASE) was designed and conducted by The Rand Corporation under contract to The Office of Policy Development and Research, U.S. Department of Housing and Urban Development (HUD). This report explains our plans as of May 1975 for the experimental housing allowance program and the accompanying research program. It reflects the original purposes and underlying assumptions of the experiment and describes the experiment's design at a time when all important details had been settled but before findings were available.

Most of the text of this report comes unaltered from the General Design Report: First Draft, published in May 1973. Subsequently, four sections of the First Draft were revised to reflect design changes; the revised sections were published separately in April and May of 1975. Although both the First Draft and the revised sections have been continuously available to interested parties, they were not widely distributed, and their existence as complementary documents sometimes confused the uninitiated. Republication of an integrated text provides future readers with a clearer account of the design whose implementation has since occupied us and whose results will be finally reported in 1981.

The First Draft summarized a year's work on the design of an experimental allowance program that would test the responses of local housing markets to a fullscale, permanent program; and the design of a market-monitoring system that would yield appropriate measures of those responses. During the summer of 1973, the First Draft was reviewed by HUD and by an outside committee of experts and, with revisions, was accepted.

by HUD and Rand as the basis for the Supply Experiment on 17 October 1973. However, certain legal issues relating to funding for the allowance program were not resolved until February 1974.

Although approval of the First Draft set the framework for the experiment, many details were yet to be specified. During the latter part of 1973 and the first half of 1974, we completed site selection, the administrative design of the allowance program, survey sample design, and survey instrument design.

In December 1972, Brown County, Wisconsin, was designated by HUD as the first of two experimental sites. Field operations leading both to housing market surveys and program implementation began in the summer of 1973. Baseline (pre-program) surveys were conducted from September 1973 through June 1974, when the Brown County Housing Allowance Office (a nonprofit corporation formed to administer the program) enrolled its first client.

In April 1974, St. Joseph County, Indiana, was designated as the second experimental site, and field operations began almost immediately. Baseline surveys were conducted from July 1974 through June 1975, and the St. Joseph County housing allowance office began open enrollment in April 1975.

By then, most details of the experimental design had performed been settled. In the spring of 1975, the first four sections of the First Draft were revised to reflect all decisions made after its publication, and the revisions were published, for convenience, under separate cover. Here, those revised sections are combined with the original versions of Secs. V through X and the original Appendices A through E. The present document thus reports our May 1975 perceptions of the purposes, methods, and problems of the Housing Assistance Supply Experiment. Our performance since then can best be measured against the plans herein set forth.

*For background on the design revisions, see HASE Staff, Final Design Model of the Housing Assistance Supply Experiment, WN-8396-HUD, October 1973; and Ira S. Lowry (ed.), Design Report: Housing Assistance Supply Experiment, WN-8396-HUD, August 1973. Approval of the program design was based on Robert Dubinsky (ed.), The Housing Allowance Program for the Supply Experiment: First Draft, WN-8330-HUD, August 1973. All are publications of the Rand Corporation.*
Between 1975 and 1980, there were of course many small changes in program standards, program administration, data collection, data management, and analytical methods. In September 1978, HUD and Rand reviewed the interim findings and agreed on a significant shift of emphasis in our analysis plan and a curtailment of the remaining data collection plan. Although we corrected a few typographical errors for this edition, we did not revise the May 1975 text to reflect subsequent changes, either large or small. Instead, we reviewed that text for passages that would be incomprehensible or misleading in the light of subsequent events. We found to our delight that such passages were rare: that readers of the present edition could be saved from any serious confusion by keeping in mind only the few important design changes that are listed below.

SITE SELECTION

- When St. Joseph County was designated as the second experimental site, only its central city, South Bend, had agreed to participate in the program. Subsequently, the remaining jurisdictions joined—so that this site, like Brown County, comprised an entire metropolitan housing market. (See p. 25.)

- Our recommendation that HUD consider a third experimental site—a neighborhood within a larger metropolitan area than either Brown or St. Joseph County—was not acted upon. Although such an addendum would have yielded important information, both design and fiscal problems argued against it. (See pp. 231 and 236.)

THE ALLOWANCE PROGRAM

- HUD preferred to fund allowance payments for the experiment from appropriations under Sec. 23 of the U.S. Housing Act of 1937 as amended. However, that legislation was designed for rental housing assistance, and the experiment was to include homeowners. An early plan, presented in the "New Deal", was
to seek separate funding for homeowner assistance under Sec. 235 of the National Housing Act as amended. Subsequently, we devised a lease-leaseback agreement for homeowner participants that made them nominally renters and so eligible for Sec. 23 assistance. That plan was presented in the April 1975 revision that is republished here. The Housing and Community Development Act of 1974 removed Sec. 23's impediment to direct homeowner assistance, so the lease-leaseback procedure was discontinued in October 1975. (See pp. 61-62, 185, 227, and 232.)

Sec. 23 also prohibited payments to single persons under 62 years of age, unless handicapped, disabled, or displaced by public action. This rule applied to the experimental allowance program until August 1977, when the rule was relaxed pursuant to the Housing Authorization Act of 1976. Thereafter, up to 10 percent of all recipient households could be single persons under 62 without disabilities or displacement histories. (See pp. 44 and 209.)

Cash allowances (in the form of checks made out to the client) are paid monthly to enrollees who occupy acceptable dwellings, regardless of their housing tenure. Two passages surviving from 1973 indicate that homeowners will receive "mortgage subsidies" and renters will receive "rent certificates." Neither device was ever used. (See pp. 185 and 232.)

THE RESEARCH PROGRAM

Housing markets in our experimental sites were monitored by means of annual field surveys addressed to a stratified probability sample of residential properties chosen at baseline. To keep that sample current, we initially proposed to select a sample of nonresidential properties that would subsequently be monitored for evidence of conversion to residential use. That plan was later abandoned in favor of an annual sample of building permits; the newly residential properties from each such sample were added to the subsequent annual survey list. (See pp. 154 and 246.)
The survey program, as described above, followed properties over time, annually interviewing each property's current owner and occupants. To help with the planned analysis of residential mobility, we seriously considered following a sample of households as they moved about within the site. Subsequently, we concluded that a mobility retrospective on the current occupants of sampled properties was adequate for our purposes. We did, however, select in each site a sample of low-income urban renter households whom we followed through local changes of residence and household splits. The records for these cases were delivered to The Urban Institute, which planned to compare them with similar records from the Housing Allowance Demand Experiment. (See pp. 130-132, 137, and 142.)

In addition to interviewing the owners and occupants of residential properties, we planned annual field reports on each sampled residential building and all neighborhoods in each site. Review of the baseline records for these surveys persuaded us that annual fieldwork was redundant. The residential building and neighborhood surveys were conducted at baseline and again three years later, in the final annual survey cycle (wave 4). In Brown County, the residential building survey was also conducted at wave 2 because of technical problems with the baseline fieldwork. In both sites, newly empaneled residential buildings were surveyed when empaneled and again in wave 4. (See pp. 31, 34, and 98.)

By annually surveying a panel of residential properties, we expected to observe housing market responses to the experimental allowance program. However, because we were unsure about the time lags in market response, we were unsure how many annual survey cycles to conduct. For planning purposes, we settled on baseline plus five years, for a total of six annual cycles. In 1977, HUD and Rand agreed that the market effects in Brown County to date had been so mild that surveying beyond the fourth year would add little
real information. A similar conclusion was reached for St.
Joseph County in 1978. Consequently, in both sites survey
data were collected at baseline (preprogram year) and in each
of the next three years.

- The original objectives of the Supply Experiment were to measure
the market effects of a full-scale housing allowance program,
specifically, supply responsiveness, the behavior of market in-
termediaries, residential mobility and neighborhood change, and
effects on nonparticipants (see p. 10). In 1976, HUD and Rand
agreed to add a fifth element, administrative studies of program
operations, focusing on effectiveness and cost.

- After reviewing midexperimental findings, HUD and Rand agreed
that the questions about market effects that motivated the Sup-
ply Experiment (see p. 10) were already answered to a first
approximation, and that HASE resources should be reallocated to
address two issues not included in the original research plan:
the dynamics of eligibility for and participation in the allow-
ance program; and the program’s effects on participants, espe-
cially on their housing consumption. This change of emphasis
was embodied in a formal agreement covering the remainder of the
experiment, signed in September 1978. **

- Section V of this report explains preliminary plans for organiz-
ing the large data sets we expected to accumulate from program
records and field surveys. The actual organization that
emerged from practical experience with those data sets differs
in many respects from that plan, though without loss of the
flexibility we sought.

---

**See Ira S. Lowry, "The Further Survey Cycle Review II," R-2155-10R;
The Rand Corporation, PN-9541-HUD, July 1976. This report, written at
the end of Wave 3 in Brown County, recommended that survey work end with
Wave 4. Events during the next year did not suggest altering that recom-
dendation, which was approved by HUD in September 1977 (after Wave 4 was
completed but before resources were irrevocably committed to Wave 5).

**The midexperimental review was based primarily on the research
findings reported in the Fourth Annual Report of the Housing Assistance
agenda for the last three years is proposed in HASE Staff, "Assessing
The analysis plans detailed in Sacs. VI through X are quite appropriately cast in the conditional mood. Many details have changed as a result of exposure to the experimental data, reconsideration of the technical possibilities, and (after 1978) a shift in research priorities.

Appendix F of the First Draft listed HASE working notes published prior to May 1973; most of them concerned either experimental design or site selection. For this edition, that list has been replaced with a current HASE bibliography, organized by topic. Readers who wish to distinguish documents published before May 1973—the perspective of this report's text—can do so by publication date.

HASE working notes (WN-series) are currently being reissued as Rand notes (N-series). Rather than alter text citations of reissued notes, we have provided a list of corresponding WN and N numbers as Appendix C. Interested readers may order publications in the N-series, R-series, or P-series from The Rand Corporation's Publications Department.

This report was prepared pursuant to HUD Contract H-1789, Task 2.1.
SUMMARY

The Housing Assistance Supply Experiment (HASE) is one among several elements of the Experimental Housing Allowance Program (EHAP) begun in 1972 by the Office of Policy Development and Research, U.S. Department of Housing and Urban Development (HUD). Specifically authorized by Congress, EHAP was undertaken to investigate whether direct cash assistance to low-income households is a feasible and desirable way to help them secure decent housing in a suitable living environment; and if so, to help determine the best terms and conditions for such assistance and the most efficient and appropriate methods for its administration.

The main purpose of the Supply Experiment is to study housing market and community responses to a fullscale housing allowance program—one that is open to nearly all low-income renters and homeowners. This report explains how, in May 1975, we expected to fulfill that purpose by conducting experimental allowance programs in two midwestern housing markets and monitoring those markets.

OBJECTIVES OF THE EXPERIMENT

The experiment's mission is to provide reliable and credible answers to the following questions about a national housing allowance program:

- Supply responsiveness. With what mix of price increases and housing improvements will the suppliers of housing services respond to the attempts of allowance recipients to increase their housing consumption?
- Behavior of market intermediaries. Will the policies of mortgage lenders, insurance companies, realtors, and home repair contractors facilitate or hinder the attempts of allowance recipients to obtain better housing?
Residential mobility and neighborhood change. Will moves by allowance recipients in search of better housing or neighborhoods alter neighborhood social patterns?

Effects on nonparticipants. Will households not receiving allowances be affected by program-induced changes in housing prices or neighborhoods? What attitudes will they adopt toward the program and its participants?

THE HOUSING ALLOWANCE PROGRAM

Housing allowances are direct cash payments to the consumers of housing, payments earmarked for housing expenditure. The recipients obtain their housing from private landlords or homesellers through normal market processes; the agency administering the allowance payments is not a party to the recipient's housing transactions and has no obligations to the supplier.

Because such a program works through the market, a realistic test of its effects must be marketwide. We propose to mount fullscale programs in each of two small metropolitan housing markets: Brown County, Wisconsin (whose main city is Green Bay), and St. Joseph County, Indiana (whose main city is South Bend). To create the proper climate of expectations, the experimental program will be publicly committed to ten years' operation, although it need not be monitored for that long. Allowances will be offered to all eligible households, and will be portable within the program's jurisdiction.

Enrollment will be open to both renters and homeowners whose incomes are too low for them to afford decent, safe, and sanitary housing. Allowance entitlement will equal the typical cost of such housing in the program's jurisdiction, minus a fourth of the enrollee's adjusted gross income. Earmarking will operate through housing standards: Payments will be made only to enrollees who occupy acceptable dwellings, as determined by periodic inspections. Arranging for repairs to substandard dwellings or moves to acceptable dwellings will be wholly the enrollee's responsibility.
THE RESEARCH PROGRAM

Data from two main sources will be used to assess market and community effects:

- **Administrative records of the allowance programs.** Program records will tell us who has enrolled, the condition of the enrollees' dwellings, the steps taken by enrollees seeking to qualify for payments, and the amounts and durations of those payments. From these records, we should be able to measure precisely the changes in participants' incomes resulting from the program and the changes in their housing expenditures after enrollment.

- **Marketwide surveys of residential properties.** To monitor market response to program-induced demand changes, we propose an annual cycle of field surveys addressed to a marketwide sample of residential properties. In the year before the program begins, and in each year thereafter, we plan to interview the current owner and occupants of each sampled property, and to inspect the property and its neighborhood. Probably, a total of six annual survey cycles will be needed to capture all important market effects.

  The surveys will collect data on the characteristics of the property, its neighborhood, its owners, and its occupants; and detailed information on property financing, operating expenses, repairs and improvements, and management policies. All respondents will be asked about their contacts with and attitudes toward the allowance program.

By following both the allowance program and the housing market over time, and making appropriate adjustments for changes in background conditions, we hope to show how program-induced housing demand translates into market responses, either price changes or quantity changes or both. In principle, our data will enable us to estimate the price elasticity of the supply of housing services for the market as a whole and for its major sectors.
An appropriately specified price elasticity of supply is a "portable" parameter of housing market behavior. It can be used in conjunction with the price and income elasticities of program-induced demand (to be estimated by the Housing Allowance Demand Experiment conducted for HUD by Abt Associates, Inc.) to analyze the probable effects of a fullscale allowance program in housing markets other than the experimental sites.

Other aspects of the research will address the mechanisms of market response: whether participants achieve housing improvement primarily by repairing dwellings or by moving, and whether their moves significantly alter neighborhood social patterns or set off a chain reaction of moves by nonparticipants; how mortgage lenders, insurance companies, realtors, and home repair contractors interact with participants who seek either to repair homes, move, or change tenure; whether housing prices or neighborhoods are altered in ways that affect nonparticipants; and how nonparticipants perceive and react to the program.
ACKNOWLEDGMENTS

GENERAL DESIGN REPORT: FIRST DRAFT

This report summarizes the work of many individuals, performed over a period of 20 months beginning in October 1971, when RAND was invited by HUD (through The Urban Institute) to explore ways of testing the supply response to a housing allowance program.

The basic concept of the experiment and the principal methods of analysis to be pursued were developed in two months of intensive work by Ira S. Lowry, C. Peter Rydell, and David de Ferranti.* Subsequent discussions with HUD led in April 1972 to a contract with RAND for design development drawing on this initial study but broadening the explicit research objectives to include analysis of the behavior of market intermediaries and indirect suppliers, residential mobility and neighborhood change, and effects on nonparticipants.

The broadened agenda and a decision by HUD as to the general scale of the experiment (metropolitanwide allowance programs in two small metropolitan areas) were reflected in a preliminary design report prepared for HUD in June 1972, supplemented by additional design papers in July.**

These documents set the framework for the experimental design that was elaborated and refined over the ensuing months. As the number of participants in the design process increased and as ideas evolved through joint efforts and staff discussion, individual contributions became less clear-cut. Appendix F lists some 35 working notes prepared during this period; their titles and authorship provide a guide to many of the individual contributions but slight others

whose work is not embodied in a specific document. Below, we try
to identify these others as well, grouping contributors to each major
element of work leading to the present report. In addition to full-
time members of the HASE staff, the listing includes other Rand em-
ployees and consultants who made substantial contributions and the
principal members of our subcontractors' staff. Within each group,
names are ordered alphabetically.

The overall design effort and the preparation of this report
were supervised by Ira S. Lowry, assisted for two critical months by
Harrison S. Campbell and Malcolm Palmatier. Most of the manuscript
and tables were typed by Geraldine Jaimovich. Graphics were prepared
by Doris Dong. Janet Deland edited the typescript and supervised
production of final copy.

GENERAL DESIGN REVIEW

In June 1973, the General Design Report: First Draft was reviewed by a panel of eleven scholars chosen jointly by Rand and HUD. The panel met for three days in Washington, D.C., for a section-by-section discussion of the proposed experimental design. Panelists' comments, often amplified by postconference memoranda, guided subsequent design revisions.* The panel consisted of the following persons:

Henry Aaron  Senior Fellow, The Brookings Institution
David M. Austin  Research Associate, Harvard-M.I.T. Joint Center for Urban Studies
Lee Bawden  Department of Economics, University of Wisconsin
Robert Crane  Department of Social Relations, The Johns Hopkins University
Frederick O'R. Hayes  Fund for the City of New York
Raymond J. Jessen  Graduate School of Management, University of California, Los Angeles
John F. Kain  Department of Economics, Harvard University
Edwin S. Mills  Department of Economics, Princeton University
Alexander M. Mood  Director, Public Policy Research Organization, University of California, Irvine
Richard Muth  Department of Economics, Stanford University
Alice M. Rivlin  Senior Fellow, The Brookings Institution; Chairman, Design Review Panel
John Wilson  North Star Research and Development Institute, Minneapolis

INTRODUCTION AND OVERVIEW: AN UPDATE OF SECS. I AND II OF THE GENERAL DESIGN REPORT

The revisions were prepared by Ira S. Lowry. Linda Ellsworth prepared the draft typescript. The draft was reviewed by Charles E. Nelson, C. Thomas Kingsley, and Robert Dubinsky. Charlotte Cox edited the text and supervised production of final copy, which was typed by Sue Garth.

THE EXPERIMENTAL HOUSING ALLOWANCE PROGRAM: AN UPDATE OF SEC. III OF THE GENERAL DESIGN REPORT

The revisions were prepared by Ira S. Lowry. Barbara M. Woodfill and Marsha A. Dade prepared the statistical tables. Doris Dong prepared the graphics. Linda Ellsworth prepared the draft typescript. The draft was reviewed by Barbara Woodfill, Robert Dubinsky, and G. Thomas Kingsley. Charlotte Cox edited the text and supervised production of final copy, which was typed by Joan Pederson.

MONITORING THE EXPERIMENT: AN UPDATE OF SEC. IV OF THE GENERAL DESIGN REPORT

The revisions were prepared by Ira S. Lowry. Timothy M. Corcoran updated Figs. 4.2 and 4.3. Ann Wang updated Tables 4.1 through 4.5. Helpful comments on the text were provided by Kevin McCarthy and Charles Noland. Doris Dong prepared the graphics. Charlotte Cox edited the text and supervised production of the note.

THE DESIGN OF THE HOUSING ASSISTANCE SUPPLY EXPERIMENT

Ira S. Lowry reviewed the collated text and wrote the new preface and summary. Charlotte Cox collated the text and Jane Abelson supervised production of the report.

This report describes and explains the principal features of the Housing Assistance Supply Experiment sponsored by the Office of Policy Development and Research, U.S. Department of Housing and Urban Development (HUD). The Supply Experiment is one element of a broader Experimental Housing Allowance Program which is intended to help the agency decide whether a national program of housing allowances for low-income families would be preferable to existing programs of housing subsidies for the same general target population; and if so, what form housing allowances should take.

Most existing programs of housing assistance for low-income families channel public funds directly to the suppliers of housing, on condition that the housing be occupied by low-income tenants. There is a contractual relationship between the public agency and the supplier which usually regulates both the housing services to be provided to the tenant and the price the tenant may be required to pay for these services.

A housing allowance program would operate differently. Public funds would be granted directly to low-income families, who would then use their increased resources to buy housing services in the local housing market. The intent of such a program would be to enable recipient families to increase their housing consumption without depriving themselves of a reasonable standard of living in other respects.

It is thus important to anticipate how recipients would respond to the opportunity afforded them by a housing allowance. For most recipients, the allowance would cover only part of total housing expenses, the recipient also contributing toward the cost of his housing. Depending on the form of the allowance (cash grant, rent certificate) and its terms (percent of actual rent, percent of income), and on the restrictions placed on the housing the recipient may occupy (rent or value level, quality level), the public contribution could be made nonfungible, partially fungible, or entirely fungible with the remainder of
the recipient's resources, and he would be given more or less discretion in choosing his level of housing expenditures.

To explore this unknown terrain of "demand" response to housing allowances, HUD is also sponsoring a Housing Assistance Demand Experiment. In that experiment, a thin sample of low-income families was selected in each of two large metropolitan areas for enrollment in a housing allowance program. Subsamples of the enrollees were given allowances on different terms, as suggested above, and their housing choices and budgetary decisions are being monitored for two years.

Because the number of allowance recipients is small relative to the total population—or even to the total low-income population—of the two housing markets in which the Demand Experiment is operating, these markets will not be noticeably perturbed by the allowance program. Neither the suppliers of housing services, nor market intermediaries, nor nonrecipient families are likely to be aware of or significantly affected by the efforts of allowance recipients as a group to obtain better housing. In this respect, the Demand Experiment is very different from a national program of housing allowances which would enroll all low-income families who chose to participate.

The Supply Experiment is intended to fill this gap, testing the market's response to a large-scale allowance program. For this purpose, two small metropolitan areas (both under 250,000 population) with different market characteristics have been selected; in each area, housing allowances have been offered to most low-income families who would probably be eligible under a national housing allowance program.* Now, the local housing market is being monitored to see what happens when program participants try to turn their augmented resources into a higher level of housing consumption.

---

* Naturally, the results of both the Demand and Supply experiments are likely to modify a priori judgments as to who should be eligible for housing allowances under a national program. The point here is simply that enrollment in the Supply Experiment will be open to a substantial fraction of the metropolitan population, including most of those likely to be eligible under a national program.
Metropolitan areas were selected as sites for the Supply Experiment because it is important that the experiment encompass an entire local housing market, both central city and adjoining suburbs, if it is to reflect the consequences of a national program for such a local market. Of course, low-income populations tend to cluster in particular locations within a metropolitan area, so enrollment will be high in some neighborhoods, low in others. But allowance recipients will not be restricted in their search for better housing to the neighborhoods in which they live at the time of enrollment. Indeed, one of the purposes of the experiment is to determine whether, given augmented resources, they will look for and be able to obtain housing improvements in their present neighborhoods, or whether they will prefer or find it necessary to search farther afield.

Compared with most programs of housing assistance for low-income families that have been tried by the federal government, the housing allowance program is both modest and ambitious. Rather than heavily subsidizing expensive new housing for a small number of low-income renters, the experimental allowance program offers modest assistance to all, or nearly all, low-income families—both renters and homeowners. The amount of assistance is designed to enable them to afford decently maintained older housing at prices that prevail in the local market.

The costs of supplying housing of a given quality vary considerably from locality to locality, and local costs will be taken into account in setting allowance levels for the Supply Experiment. However, where direct comparisons have been made, it appears that older housing (i.e., housing built prior to World War II) can be upgraded and kept in good condition at about half the annualized cost of new public housing. Present estimates indicate that a housing allowance averaging $700 to $800 a year (in 1974 dollars), matched by a reasonable contribution from the recipients' other resources, would enable all low-income

*In one of our two experimental sites, circumstances have impelled us to begin with the central city as the jurisdiction of the experimental allowance program. We hope soon to extend the program to the remainder of the metropolitan housing market, all of which is to be monitored in any case.
families in most communities to afford decent housing, so defined. If the recipients' contributions ran as high as they do in federal public housing, a given total federal contribution would enable five to eight times as many households to obtain decent housing under such an allowance program.

The lower cost per assisted family of a housing allowance program would be offset by broader participation. Under Supply Experiment standards, we estimate that nearly a fourth of all households in each experimental site are eligible for assistance, though we expect only 50 to 75 percent of these to apply.* In a metropolitan area with 250,000 inhabitants (75,000 households), a permanent program based on our standards would probably enroll about 10,000 to 12,000 households. Assuming an average annual allowance of $750 per household, payments would total $7.5 to $9.0 million annually.

The fraction of total allowance payments that would reappear as a net addition to housing expenditures depends very much on the form of payment and the restrictions imposed on the housing choices of allowance recipients. Assuming that at least half of all allowance payments are devoted to increasing housing expenditures (as opposed to substituting for preallowance housing expenditures), $9 million in annual allowance payments implies an increase in metropolitanwide housing expenditures (by both homeowners and renters) of 5 percent at most in a metropolitan housing market with 250,000 inhabitants. While this is a large enough increase to perturb the market, it is well within the range of experience with "natural" market shifts occurring over a period of two or three years. Thus, there is no reason to anticipate a severe metropolitanwide dislocation of the housing market. The effects would be focused on the sector of the market that supplies housing to families of low and moderate incomes, where housing expenditures might increase by as much as 30 percent, or even more in very low-income neighborhoods.

*This has been the general experience of federal transfer programs with a means test, even those that have long been in effect. It is partly explained by the fact that many who are nominally eligible are entitled only to small amounts of assistance.
The Housing Assistance Supply Experiment is designed to reveal the dynamics of market response to such an increment of low-income housing demand by actually injecting the demand increment and monitoring the market thereafter. An experiment is appropriate because there is substantial uncertainty and even fundamental disagreement among housing economists and other interested parties as to the probable effects of a national housing allowance program with the characteristics described above.

Section II of this report lists four clusters of critical questions about the effects of such a program which we believe can be reliably answered by the Supply Experiment. * Briefly, they include questions about the effectiveness of the program as a means of inducing housing improvements and the related possibilities for inflation in housing prices; about the behavior of market intermediaries and others in an allowance-stimulated market; about residential mobility induced by the program and the consequent redistribution of local populations; and about the effects of the program on nonrecipients and their attitudes toward it. Then, Sec. II describes the general strategy of the Supply Experiment in seeking empirical answers to these questions. Finally, it provides a chronological overview of the contemplated experiment from site selection through termination.

The proposed design of the experimental allowance program is presented in Sec. III. This design, as the basis for disbursement of large amounts of public funds over a period of ten years, necessarily reflects compromises among conflicting requirements: different views of the feasible and the desirable characteristics of a national program, constraints imposed by available sources of funding, practical problems of creating a local organization to administer the program, and features inappropriate to a national program but helpful for an experiment whose purpose is to produce information.

* Answers to other questions bearing on the preferred program design and probable consequences of a national program will be sought by HUD in the Demand Experiment, or in a third Administrative Agency Experiment, which tests various institutional arrangements for delivering housing allowances.
Section IV describes our proposed monitoring program, which relies partly on administrative records of the allowance program but principally on six annual cycles of field surveys addressed to a large sample of residential properties, their owners, and their occupants. The sample is a longitudinal panel, designed so that successive annual observations will enable us to track changes in the housing market as they occur. The field-survey agenda is technically complex and in some respects risky; if successful, it will provide data of a kind and quality without precedent in housing research.

The central purpose of these field operations is to produce systematic data concerning the effects of the allowance program and related events on the local housing market. Section V describes our plans for assembling these data into permanent machine-readable files whose overall organization permits data to be abstracted, linked to data from different sources or different points in time, and manipulated to serve a wide range of analytical requirements. The section closes with a very brief prospectus for each of the major analyses to be undertaken, showing its dependence on data from each of the major files.

Sections VI through IX enlarge upon these analytical prospectuses. Each section presents a plan for analyses related to one of the major research topics with which the Supply Experiment is charged. In each case, we describe the policy issues as we understand them and pose a set of specific research questions whose answers should assist in policy determination. Then we describe the sources of data and the forms of analysis we propose to use in seeking answers to these questions. The level of exposition here is nontechnical; our purpose is to enable the general reader as well as the specialist to judge whether the analytical approach is reasonable in its broad framework, not to present detailed statistical models.

In Sec. X, we evaluate the probable success of the Supply Experiment in terms of the reliability and credibility of the evidence it will supply concerning the effects of a national housing allowance program. Our discussion here focuses on the measurement of allowance-induced changes in the price and quantity of housing services supplied
at each experimental site and on inferences from this evidence to the corresponding effects of a national program.

The emphasis in Sec. X on supply response to the experimental allowance program does not imply lack of interest in the other three research topics included in our charter; rather, it reflects our conviction that those topics present lesser analytical and inferential challenges. The difficulties in measuring supply response in each experimental site and extrapolating from these findings are sufficiently impressive that we have included in this report a series of technical appendixes designed to demonstrate that we have given careful thought to these problems and see our way to their solution.

These appendixes include a mathematical model of housing deterioration under alternative maintenance policies (Appendix A); a detailed specification of the accounting system by which we propose to measure supply response (Appendix B); a method for estimating parameters of the production function for housing services (Appendix C); a method for measuring changes in the prices of factors used in the production of housing services (Appendix D); and a technique for combining data from the demand and supply experiments to estimate the effects of housing allowances of various kinds in local housing markets other than the experimental sites (Appendix E).

This report does not represent the end of the process of experimental design, or even the full extent of the work so far completed. Technical documentation of analysis plans for each of the four research topics continues, with increasing detail at each step. Other working notes, listed in Appendix F, provide details on many subjects here treated only briefly or not at all. The material selected for the present report is adequate, we think, to provide the reader with the information he needs to understand the experimental strategy and to evaluate it in relation to the experimental purposes.

*Working notes published before the current revision of the Ginn Design Report frequently present views on experimental design that were subsequently modified. Where they conflict with material in this report, it should be assumed that they are in that respect obsolete.
In its current revision, this report reflects an experimental design that has been approved by HUD as the basis for Rand's work over the next five years. As might be expected for an experiment of this magnitude and duration, the design evolved through many iterations in which the experimental mission, the resources available, legislative constraints, and methods for gathering and analyzing data all were mutually adjusted by negotiations, compromise, and discovery of new alternatives.

The process began with a preliminary design study prepared by Rand late in 1971 under subcontract to the Urban Institute.* In April 1972, Rand contracted directly with HUD to design and implement the Supply Experiment. Under this contract, we completed a second preliminary design study in June 1974.** Over the following year, design details were worked out in consultation with HUD, and the precursor of the present volume was published in May 1973.*** That document was carefully reviewed both by HUD and by an independent panel of experts during the summer of 1973**** and was subsequently accepted by HUD, subject to certain agreed-upon changes and also to the resolution of certain legal questions about the scope of the experimental allowance program.

The legal questions were satisfactorily resolved in February 1974. In June 1974, however, stresses on the experiment's budget for data gathering and analysis led to additional changes in the experimental

design that promised to reduce costs without major damage to experimental purposes.

In the meantime, the experiment got under way in the field. In Site I, baseline surveys were completed in April 1974 and the allowance program began general enrollment in June. As this section is written, baseline surveys in Site II are nearing completion and enrollment in the allowance program has begun there also.

Thus, the present report is a revision and update of the draft General Design Report issued in May 1973. It incorporates all design changes subsequently agreed upon by HUD and Rand. It also reflects much more concrete information about the experimental sites, only one of which had been selected and neither of which had been surveyed in May 1973. Finally, the experiences of selecting samples and conducting baseline surveys in both sites have modified some of our views of research strategy or tactics.
II. AN OVERVIEW OF THE SUPPLY EXPERIMENT

All of the experiments planned as part of the Experimental Housing Allowance Program are intended to provide information bearing both on the optimal design of a national program of housing allowances and on the merits and demerits of such a program as a means of improving the housing conditions of low-income families. HUD's decision to mount separate Demand, Supply, and Administrative Agency experiments is motivated by considerations of efficiency. Each experiment is designed to answer specific questions and to capture specific kinds of information; the various findings are to be integrated analytically.

EXPERIMENTAL OBJECTIVES

The mission assigned to the Supply Experiment is to provide reliable and credible answers to four clusters of questions about the effects of a national housing allowance program:

1. Supply responsiveness. How will the suppliers of housing services—landlords, developers, and homeowners—respond to the attempts of allowance recipients to increase their housing consumption? Specifically, what mix of price increases and housing improvements will result? How long will these responses take to work themselves out to a "steady state"? How will these responses differ by market sector?

2. Behavior of market intermediaries and indirect suppliers. How will mortgage lenders, insurance companies, and real estate brokers respond to an allowance program? Will their policies facilitate or inhibit the attempts of allowance recipients to obtain better housing and those of landlords to improve their properties? What happens to the availability, price, and quality of building services and repair and remodeling services? What seem to be the reasons for any observed changes in institutional or industrial policies?
3. **Residential mobility and neighborhood change.** In their attempts to find better housing (or better neighborhoods), will many allowance recipients relocate within the metropolitan area? What factors influence the decision to move or to stay? What types of neighborhoods will the movers seek and succeed in entering? Do moves by allowance recipients set in motion a chain of moves by nonrecipients--either into neighborhoods vacated by recipients or out of neighborhoods into which recipients have moved?

4. **Effects on nonparticipants.** How will households not receiving housing allowances--particularly those whose incomes are within or just above the range of eligibility--be affected by the program? Specifically, will the increased housing demands of allowance recipients cause an increase in housing prices for nonrecipients? Whether or not such price increases occur, will nonrecipients perceive personal hardships or benefits from the program? How will they perceive and react to allowance-stimulated neighborhood changes?

The answers to these questions are interdependent, especially as they relate to the rental housing market. Whether a landlord chooses to raise rents, and whether he also chooses to offer his tenants improved housing, depends on his perceptions of changes in market demand and of the alternatives available to his tenants. If he wishes to undertake capital improvements, he must usually seek outside mortgage financing. The lender must judge that the future stream of revenue will be adequate for debt service, that foreclosure would not result in capital loss, and that the property is and will continue to be insurable against physical damage or destruction. The extent to which their present landlords raise rents and improve physical facilities and services will affect the allowance recipients' decisions to stay or to seek other quarters better suited to their augmented budgets and housing preferences. If they seek better housing elsewhere, they are likely to be competing with nonrecipients for housing previously beyond their means.
In the homeownership market, answers to the four research questions are also interdependent, but less so than in the rental market. The supplier of housing services is the homeowner himself, and his signals for action come more directly from the allowance program. An eligible homeowner may improve his house to program standards in order to qualify for allowances, he may sell one home and buy another, or he may sell and become a renter; but the first alternative seems by far the most likely. In that event, his decision will doubtless hinge on his personal estimate of the costs and benefits of participation. However, he may need a home improvement loan or the services of a remodeling contractor, so the policies of market intermediaries and indirect suppliers may indirectly determine whether a homeowner can meet program standards and at what cost. His decisions may also be affected by trends in neighborhood deterioration or improvement which are influenced by the allowance program, and his decision will in turn modify any such trend. And these trends in turn are likely to affect the values of properties belonging to nonparticipants, for better or for worse.

Not only are the answers to our research questions interdependent, they are likely to change over time. Those initially enrolled in the program are unlikely to react immediately or simultaneously to their augmented housing budgets, so the demand signals to landlords will be delayed and at first unclear. The landlords in turn will need time to respond—whether with rent increases or housing improvements—and as market signals clarify, these responses may change. The actions of landlords may in turn modify the perceptions and policies of market intermediaries and indirect suppliers. All these events, in turn, may perceptibly change the alternatives open to allowance recipients and the consequences of their choices for others (e.g., nonrecipients).

Finally, different groups within the relevant populations of landlords, market intermediaries, allowance recipients, and nonrecipients are likely to respond differently to a given stimulus, so that an "average" response may conceal important information. The structure of the local housing market and its initial conditions may also influence response patterns. The incidence of rental tenure (or of ethnic
minorities) may condition responses by both renters and homeowners (or by blacks and whites). And a market initially characterized by excess demand would respond differently from one characterized by excess supply.

Thus, though the questions can be phrased simply, the answers are likely to be both complex and highly dependent on local circumstances. No feasible set of experiments can embrace all plausible variations in circumstances or trace out all consequences. Yet if a national program of housing allowances is a serious possibility, some information about its possible consequences is manifestly better than none, and limited empirical evidence can be extended analytically to predict the unobserved.

**EXPERIMENTAL STRATEGY**

In our view, the most difficult issues to be resolved by the Supply Experiment are the questions of supply responsiveness: how the suppliers of housing services would respond to the increased effective demand for housing by low-income families that a national housing allowance program would generate.

In general, when the demand for a commodity increases, suppliers respond with some combination of increased output and higher prices. Also, in general, the short-run and long-run responses differ. The movements in prices and quantities over time would ordinarily reflect the amount of the shift in demand, the initial supply conditions (e.g., the size of the unsold inventory), and the costs encountered by producers when they attempt to increase output. Our task is to design an experiment that shows how these general principles apply in a low-income housing market when demand is stimulated by housing allowances.

As we see it, the experimental design must cope with six basic problems:

1. Because a central feature of the contemplated housing allowance program is its dependence on market processes, the experiment must create, on a small scale, the essentials of the market process: buyers and sellers of housing services reaching mutual accommodation through voluntary action in response to market signals.
2. The increment of effective demand resulting from experimental housing allowance payments must be sufficiently focused geographically and sufficiently stable over time that the resulting market signals will be perceptible to suppliers and will not be discounted by them as purely transient phenomena.

3. Changes in the flow of housing services are difficult to quantify; most measures that seem operationally feasible confound price and quantity changes, a result that would defeat a primary purpose of this experiment.

4. Market responses must be observed for a long enough period of time to detect not only short-run behavior—which may be critical to the political success of a housing allowance program—but enough of the longer-run trend to permit strong inferences as to the durable consequences of such a program.

5. Experimental controls must be adequate to distinguish consequences of the housing allowance payments from those of independent background events—things that "would have happened anyway." Some of these events may be national forces that would impinge generally on a national program; others may be purely local factors that impinge only on the experiment.

6. The results of the experiment must be intelligible and credible not only to professional analysts and housing experts but also to the broader constituency whose support would be essential to passage and implementation of a national program.

This focus on creating experimental conditions that will enable us to measure housing supply response—price and quantity changes attributable to the allowance program—does not imply neglect of the other three clusters of questions to which the Supply Experiment is addressed. One of those, measuring the impact of the program on non-recipients, is manifestly dependent on our ability to measure housing price and quantity changes in general. Another, the behavior of indirect suppliers and market intermediaries, is of interest primarily because their behavior will help to explain the observed pattern of supply responses. While the residential mobility of allowance
recipients can be recorded without accurate information about housing price and quantity changes, it is reasonable to expect that such movements will both reflect and affect supply responses in ways we will want to comprehend. Our point is simply that an understanding of the dynamics of supply response is crucial to the evaluation of housing allowances as a national program, and that, of all the kinds of information to be gathered by the Supply Experiment, reliable measurements of housing price and quantity changes will be the most difficult to obtain. They thus become the key to the experimental design.

Our strategies for dealing with the six problems listed above are spelled out in the remainder of this report. However, a brief preview at this point may help to orient the reader.

Creating a Market Context

There are several existing housing programs that entail direct negotiations for housing improvements between a public agency and private landlords in return for guaranteed rent payments for some term of years. Careful study of such transactions, or an experiment designed along similar lines, would provide evidence of supply responsiveness under conditions of certainty about future revenues and under bilateral bargaining. We do not think that such evidence would be pertinent to the outcome of a national housing allowance program, which is critically dependent on normal market processes that entail both uncertainty and multilateral bargaining. To discover how the market responds to housing allowances, we think it is necessary to mount an experimental allowance program and monitor the market response. The difficulty lies in finding a way to do this on an economically small scale.

In our initial experimental design, we proposed selecting small urban neighborhoods (about 5,000 housing units) as sites for the Supply Experiment. These were to contain predominantly rental housing and a population whose income distribution was such that roughly half the households would be eligible under the standards of a national program.

*Lowry, Rydell, and de Ferranti, Testing the Supply Response to Housing Allowances, Sec. III.
Alternatively, only residents of these neighborhoods might be enrolled in the experimental allowance program, or enrollment might be extended to the entire metropolitan (i.e., housing market) area.

To limit enrollment to the selected neighborhoods would create difficulties both in managing the experiment and in interpreting its results; this alternative was proposed because we were uncertain about the fiscal resources available for the experiment. Since HUD made funds available to enroll all eligible households in each of two small (under 250,000 population) metropolitan housing markets, the present design is based on metropolitanwide enrollment and market monitoring.

Providing a Perceptible and Stable Demand Stimulus

However, our reasons for singling out high-enrollment neighborhoods for special attention persist. The demand stimulus provided by our experimental allowance program will not affect all sectors of the housing market equally; it is unlikely, for example, that the owners of luxurious apartment houses or expensive single-family homes will perceive any demand changes related to the allowance program. Where there is no demand stimulus, there can be no supply response. Consequently, we propose to concentrate our monitoring resources on sectors of the housing market where we expect the allowance program to have the most impact. This strategy leads to a somewhat unusual survey sample design.

To achieve the stability of expectations that would be associated with a permanent national housing allowance program, we sought and obtained HUD's commitment to a ten-year experimental allowance program at each site, even though we expect to monitor their housing markets only for a shorter period. This commitment does not entail an allowance guarantee for that period to individual households, who may become ineligible because of increased income or for other reasons; nor does it entail any guarantee to specific landlords, all of whom must compete in the marketplace for allowance-receiving tenants. It only guarantees a fairly stable increment to low-income housing demand in that housing market for the ten-year period.

Allowances will be portable within the program's jurisdiction. Recipients who leave that jurisdiction will lose their entitlement.
To safeguard against allowance-stimulated immigration, only those actually living there will be enrolled, and those who arrive after the beginning of enrollment will not be guaranteed a place in the program.

Measuring Changes in the Flow and Price of Housing Services

To measure supply response, we propose to track a panel of residential properties over the term of the experiment, surveying each property annually to learn about changes in rental revenues, physical changes in the structure itself, changes in the services and maintenance provided by the owner, and changes in the levels of satisfaction expressed by the tenants.

We have devised a method of accounting for annual changes in the flow of real factor inputs used in the production of housing services that we believe will enable us to distinguish in policy-relevant detail between rent increases and price increases—the former including payments for additional housing services, the latter being the inflationary effects of the allowance program and other factors.

It is also important to note that these annual surveys are not confined to housing occupied by allowance recipients. A significant feature of housing allowances is their portability; no owner of residential property can be sure that he will be able to capture or hold allowance recipients as tenants, and some may not even wish to try. We expect that some substandard housing, not easily improvable, will be withdrawn from the market because it is no longer marketable to those who have become allowance recipients and there are no other customers in sight. In sectors of the market where allowance recipients are seeking housing, rents and sales prices are likely to increase for recipients and nonrecipients alike. If our experiment is to capture all these effects, we must monitor the housing market, not just housing units occupied by allowance recipients.

Duration of the Monitoring Program

By analogy to experience with other markets subjected to sudden increases in demand, we expect the strongest inflationary pressures to appear early in the experimental allowance program, moderating over
time as suppliers of housing services perceive the profitability of increasing their outputs and actually do so. Thus, the least encouraging information about the effects of a housing allowance program will be the first information obtained. We think it is important to monitor the local housing markets long enough to observe the more durable consequences of the program.

We now have little solid evidence to assist us in estimating response lags in the housing market. We have constructed a scenario whose elements seem consistent with related experience; it suggests to us that, in the absence of other disturbances, a local housing market ought to adapt fully to a permanent increment of demand in about five years. We therefore propose five years as the appropriate duration of the monitoring program at each experimental site; however, no immutable decision on this score need be made now, and evidence from the experiment itself will help us to judge whether the monitoring period should be curtailed or extended.

**Experimental Controls**

Since a metropolitan housing market is the subject and unit of observation for the most important issues to be explored by the Supply Experiment, classical methods of experimental control (matching groups of treated and untreated subjects, or conducting the experiments in a rigorously controlled environment) are either hopelessly expensive or institutionally infeasible. To distinguish consequences of the experimental housing allowance program from consequences of independent background events, we must rely primarily on before-and-after comparisons, on comparisons of events in market sectors which differ with respect to participation by allowance recipients, and on direct measurement of background forces whose effects can be formally modeled along with those of the allowance program.

Unless there is a major natural disaster in one of our experimental sites, or a powerful exogenous shock to its economy, we believe that

---

*Lowry, Rydell, and de Ferranti, Testing the Supply Response to Housing Allowances, Sec. IV.*
analysis along the lines suggested above will be adequate to distinguish the role of the experimental allowance program in shaping observed events: supply response, behavior of market intermediaries, residential mobility, and effects on nonparticipants. While we do foresee limits to our ability to quantify the relative responsibilities of the allowance program and of other forces for certain kinds of events, we feel confident that we can narrow the range of ambiguity at least enough to support a fortiori conclusions that are adequate for policy analysis.

Credibility of Experimental Findings

If the Supply Experiment is to influence national housing policy, it is essential that experimental findings be understood and believed both by technical specialists who are able to follow the details of experimental and analytical methods and by a broader audience who will rely upon common sense to interpret and qualify the reported results.

By matching the experimental allowance program to the scale and essential features of a national housing allowance program, and by encompassing the entire metropolitan housing market in the allowance program and in our monitoring plan, we think we will achieve the basic requirements of experimental credibility. Our monitoring program is both broad in scope and intensive in detail: the major contingency that might threaten its credibility is a wholesale failure of cooperation by landlords, tenants, or allowance recipients. Our analysis plans have been designed with a view to yielding findings that are intelligible to a lay audience while embodying the methodological rigor needed to satisfy professional analysts.

These points bear on the credibility and reliability of our account of the consequences of the experimental allowance program conducted in each of two small metropolitan areas. A further question is whether this evidence will support generalizations about the effects of a national housing allowance program. There, the ground is more treacherous.

Manifestly, a sample of two cases provides no basis for statistical inference to the nation as a whole. However, by choosing our sites carefully so that they differ in what are generally acknowledged
to be the critical features of housing markets, we can strengthen the basis for judgmental inference. The sturdiness of such inference will depend in part upon whether experimental outcomes in the two sites are similar or radically different.

Finally, our analysis plan provides for the estimation of behavioral parameters (e.g., the price elasticity of the supply of housing services, by market sector) that have a certain portability. Combining these parameters with similar ones from the Demand Experiment (e.g., the price and income elasticity of the demand for housing services), it is possible to model the general effects of a housing allowance program in housing markets other than those that served as experimental sites.

IMPLEMENTING THE EXPERIMENT

Above, we have tried to provide the reader with a clear sense of our experimental objectives and of our general strategy for achieving these objectives. Here, we offer another view of the overall framework of the experiment, an account of its implementation that places the major elements of design in chronological perspective. Other sections of this report, organized topically, fill out the tactical details of experimental design and methods of analysis.

Site Selection

As stated earlier, HUD agreed to fund the Supply Experiment in two small metropolitan areas, with metropolitanwide enrollment of low-income

---

The decision to mount the experiment in two small metropolitan areas does limit the kinds of housing markets available as sites. Some market configurations appear only in large metropolitan areas (e.g., spatially extensive ethnic ghettos, high incidence of rental tenure, high incidence of multiple dwellings). Whether these features would have a major effect upon the outcome of a housing allowance program is an open question. Because big-city housing problems are the focus of so much policy attention, mounting the Supply Experiment in a third site, a low-income neighborhood in a very large metropolitan area, would greatly strengthen small-city findings. Here, we think the issues to be investigated could be served satisfactorily by an allowance program restricted to residents of that neighborhood; but doing so would require more powerful methods for controlling participation by immigrants than are needed in our metropolitanwide allowance programs.
families in the experimental housing allowance program. Most of the potential participants in a national housing allowance program live in large metropolitan areas; in 1970, three-fourths of the nation's metropolitan population and one-half of its total population lived in SMSAs* with 500,000 or more inhabitants. For budgetary reasons, Supply Experiment sites were restricted to smaller SMSAs, with the upper limit set at 250,000 inhabitants; however, we sought sites with as much structural resemblance as possible to the larger SMSAs.

Pursuant to this objective, we classified the nation's SMSAs in terms of characteristics that seemed pertinent to the effects of a housing allowance program and examined the resulting distributions, both in terms of numbers of SMSAs and total population.** We concluded that the two most critical variables, aside from size, were the economic vitality of the central city and the incidence of ethnic minorities in the central-city population. Using the limited data then available from the 1970 Census of Population, we measured the first variable by the intercensal rate of population growth in the central city, and the second by the percentage of blacks in the central-city population.

Table 2.1 shows how the universe of SMSAs is distributed in these terms. While the number of SMSAs in each of the four cells of the table is approximately the same, the greatest share of metropolitan population falls in the slow-growth/high-black category. We therefore proposed to select one site from among the metropolitan areas of this group.

Of the three remaining categories, none is powerfully dominant either in number of cases or total population. We concluded that the greatest contrast to our first choice would be obtained by selecting the second site from among those SMSAs in the fast-growth/low-black category.

---

NOTE: Growth rate and ethnic categories are divided at median values for all 1970 SMSAs.
Within each of these two categories, we examined the variation of other housing and population characteristics with size of place. The characteristics included the incidence of other minority groups in the population, housing tenure, the incidence of multiple dwellings, vacancy rate, median housing rents and values, incomes, the unemployment rate, and the incidence of welfare recipiency. Only housing tenure and the incidence of multiple dwellings showed a strong correlation with size of place; we concluded that, with these exceptions, SMSAs of under 250,000 population provided a fairly representative assortment of market configurations.

The remaining steps focused on the small SMSAs in each group: 18 in the slow-growth/high-black category and 37 in the fast-growth/low-black category. Systematic screening procedures, each step reflecting information gained from increasingly detailed investigation, eliminated places that did not really fit their assigned categories (e.g., intercensal growth rate distorted by annexation), that would be administratively cumbersome (e.g., SMSAs that straddle state lines), or that were unsuitable for the experiment because of some unusual characteristic (e.g., a large military or college population).

In the most important step, we rated each place not only on the two major dimensions of difference (centrality, city growth rate and incidence of blacks) but on the other housing and population characteristics mentioned above. A scoring system awarded the best scores to places in each group whose characteristics were close to the median values for all SMSAs (not just small SMSAs) in that group. Those with low scores were eliminated from further consideration. Those with high scores were visited by a team of Rand and HUD personnel to gather additional data on their suitability for the experiment and to appraise the level of local interest in participating in the experiment.* The information thus gathered was reviewed jointly by Rand and HUD, and the candidate sites on each list were ranked in order of suitability.

To summarize, our site-selection procedure was designed to select one site whose central city has a slow or negative rate of population growth and contains a large black minority, and another site whose central city is growing rapidly but whose population is virtually all white. Within these two categories, we sought places that were typical of their groups in other respects, avoiding extreme or unusual cases. Thus we hoped to obtain powerful contrasts in the housing market and population configurations of our two sites, despite the limit imposed on SMSA size.

While the SMSA was the nominal unit in our search for suitable sites, the actual geographical boundaries of allowance-program enrollment need not be the SMSA boundaries. Instead, they should reflect the spatial extent of a housing market whose core is the central city of the SMSA, also taking into account the administrative conveniences of operating the experiment within fewer rather than more local jurisdictions.

In the fast-growth/low-black category, site selection went smoothly. Our first choice was Brown County, Wisconsin, whose central city is Green Bay. Negotiations with local officials had progressed far enough by the end of 1972 to enable us to designate Brown County as Site I of the Supply Experiment, although not all townships in the county had yet agreed to participate. An annual contributions contract funding a countywide allowance program there was signed early in 1974, after various legal issues relating to program scope were resolved by HUD's General Counsel.*

Selecting a slow-growth/high-black housing market for Site II proved more difficult. Our first choice was Saginaw, Michigan, but we were unable to secure the participation of key suburban jurisdictions there. Similar problems were encountered in Clark County, Ohio, and St. Joseph County, Indiana. In the end, Rand and HUD agreed that

the most promising site was St. Joseph County, even though only its central city, South Bend, was then willing to participate in the program. An annual contributions contract funding the allowance program there was signed in the fall of 1974.

Although St. Joseph County answers quite well to the design specifications for Site II of the experiment, restricting the allowance program to its central city manifestly hampers our research plan and specifically weakens our ability to reach conclusions about the residential redistribution that would occur under a national program without such jurisdictional limits. However, we judged that we were unlikely to do better elsewhere and that there was a good chance in this case that the program could later be extended to other jurisdictions in the county. In any event, we plan to monitor the housing market throughout the county. Even assuming that the program is permanently confined to South Bend, we think that most of our research objectives are attainable.

With that qualification, our experimental sites each consist of a metropolitan housing market whose boundaries run through thinly settled rural territory. Tables 2.2 and 2.3 summarize and compare the demographic, economic, and housing-market characteristics of Brown and St. Joseph counties, as reported by the 1970 Census of Population and Housing.* It is worth noting that by September 1973, Brown County had acquired about 4,000 additional households; and by September 1974, St. Joseph County had lost about 1,800 households, both places continuing in their pre-1970 population trends.

Baseline Surveys

At each site, we undertook field surveys to gather systematic data on the population, the housing stock, and housing-market conditions immediately prior to the commencement of the allowance program. For this purpose, we selected a stratified random sample of residential properties, including both rental and owner-occupied housing. The

stratification distinguishes sectors of the housing market that we expect either to be differently affected by the allowance program or to respond differently to allowance-stimulated housing demand. Sample sizes are largest in those sectors of the market within which we expect the most activity by allowance recipients. *

For each property in the sample, we assembled (from tax records and field observation) a detailed description of the property and the neighborhood in which it is located. For each rental property, interviews were sought with the landlord and all or some of his tenants. For each owner-occupied home, an interview with the owner-occupant was sought.

Each landlord interview was designed to elicit information about the owner's personal characteristics and his experience in real-estate management, and about the history and prospects of the sampled property, its current condition, its mortgage financing, and (for the preceding year), its rental revenues and its maintenance and operating expenses. Finally, we asked about management and tenant-selection policies and about plans for the property.

Interviews of tenants and homeowners were similar to each other in seeking information on family composition, income and employment, and life-style. In addition, the respondent was asked for an account of his moves during the preceding five years and of the housing, family, and employment circumstances related to each move. Finally, there were a number of questions about the characteristics and condition of the housing unit and its environs. Tenants were asked about contract rent, utility payments, and other housing expenses incurred during the preceding year; homeowners were asked for information about mortgage financing, taxes, insurance, utility expenses, and outlays for maintenance and repairs.

Since the probability of selecting each sample element is known from the sampling procedure, we will be able to estimate from the sample

---

* See Sec. IV, below, for details of sample design and survey instruments.
data the incidence of observed characteristics of housing, landlords, tenants, and homeowners in the entire metropolitan area. Of particular importance, we will be able to estimate the annual revenue from and cost of production of housing services within the experimental site, by market sector and for the market as a whole.

The Housing Allowance Program

When the baseline surveys were nearly complete, applications for enrollment in the housing allowance program were invited from low-income households in each site. The opening of the program was attended by considerable publicity, and there is a continuing effort to inform the public about the nature of the program, the standards of eligibility, and the levels of benefits.*

The program will last ten years in each site. During that time, any eligible household may enroll and receive assistance, within the limits on program size specified by the annual contributions contract. (These limits, however, allow open enrollment for the foreseeable future.) The program is open to both renters and homeowners, and eligibility does not depend on prior housing conditions or prior housing expenditures.

Monthly allowances are offered to eligible families in amounts that increase with household size and vary inversely with income from other sources. Benefit schedules are designed to enable all participants to afford safe, sanitary, and decent housing units of adequate size, taking into account the local cost of such housing. Generally, the recipient will have to supplement the allowance with other funds to meet his housing expenses, so that the marginal dollar of expenditures will come out of his nonallowance income.

Program participants choose their own housing and may move freely within the program's jurisdiction without loss of entitlement. However, each home they occupy must be evaluated by the agency administering the

*See Sec. III, below, for additional details about the organization and administration of the allowance program.
program, and no payments will be made to an eligible household while it occupies a substandard housing unit. This provision limits the fungibility of the allowance, ensuring that those formerly occupying substandard housing will be impelled to improve it or to find a better home in order to qualify for program benefits.

Although nondirective counseling is offered to each enrollee, it is his responsibility to find suitable housing, to arrange terms and conditions of occupancy, and to meet his obligations to the landlord or mortgage holder thereafter. The allowance agency has no direct dealings with landlords or lenders and no contingent obligations to them. Disputes between landlords and tenants or between homeowners and mortgage holders are subject to normal civil procedures.

Enrollment in the program assures the enrollee of a monthly allowance payment for the remainder of the ten-year period, provided he remains eligible and abides by program rules. However, the amount of the payment may increase or decrease as his nonallowance income and his household size change. Recertification of eligibility and recomputation of benefits is to occur at intervals of six months. The housing occupied by each allowance recipient is reevaluated annually, and payments will be suspended if the unit is found to have deteriorated below the standard.

Postenrollment Surveys

We plan to monitor the local housing market and the activities of allowance recipients for five years after enrollment in the allowance program begins. There are several elements to our monitoring plan. First, we will follow most of the residential properties in the baseline sample described above by means of an annual cycle of field surveys addressed to the property itself, to the owner, and to the current tenants. Second, we will follow each program participant by means of administrative records. Third, we plan several small-scale surveys to pursue special issues. Fourth, a resident observer at each experimental site will be charged with informal monitoring of public events and attitudes bearing on the experiment.
The Panel of Residential Properties

Following the baseline surveys described above, we will select a panel of about 2,000 residential properties from among those with adequate baseline records. Each year thereafter, this panel will be updated by a sample of properties newly converted to residential use, drawn from building-permit records. Thus, the panel will always be representative of the entire housing stock of the experimental site.

Each year, fieldworkers will visit each property on the panel and try to interview its owner and occupants, seeking data comparable to those collected at baseline. As at baseline, up to three survey instruments will be administered:

- **Survey of Residential Buildings.** The baseline building survey will be repeated each year, with emphasis on detecting changes since the preceding year in the use or characteristics of the property, the physical condition of the structures on it, and the characteristics and condition of the immediate neighborhood.*

- **Survey of Landlords.** We propose to reinterview owners or managers of all rental properties in our sample each year, to obtain a record of rental revenues and outlays for building maintenance and operations that is comparable to the data gathered at baseline. We will also inquire about capital improvements made during the year and their cost, and we will update our information about mortgage financing, insurance, and taxes.

The financial data to be gathered in these annual surveys are designed to enable us to estimate for each property the annual changes since baseline in rental revenues and in total costs of production. Deflating the latter by means of factor-price indexes, we expect to be able to estimate changes over

---

*Actually, some of the information described here will be gathered in a separate operation called "fieldlisting."
time in real factor inputs used to produce housing services, and to compare these with concurrent or lagged changes in revenue. Thus we arrive at measures of the supply response to changing demand conditions in the marketplace.

Other aspects of this survey are aimed at enlarging our understanding of the respondents' housing investment and operating policies and of their perceptions of the changes that are occurring in the housing market as a result of the allowance program and of other factors.

- **Survey of Tenants and Homeowners.** We plan annual interviews of the current occupants of each housing unit selected for inclusion in the panel. In many instances, these will be the same households interviewed in previous years. In other cases, the previous respondent will have moved, and a new occupant will be interviewed. Because our sample of residential properties will be kept representative of the site's housing stock, our sample of households will be kept representative of the site's population of households.

  In reinterviews, our survey will emphasize changes in household composition, income, and employment: changes in the characteristics or condition of the dwelling unit, contract rent, and other housing-related expenditures; and changes in attitudes toward the housing unit, the landlord, the neighbors, and the neighborhood. When we encounter a new tenant, the survey instrument will seek the full range of information captured at baseline. For homeowners, the annual survey will also seek a year's record of housing operating and maintenance costs and mortgage and insurance data similar to those sought from owners of rental property.

  In these surveys, our principal purposes are to obtain the data about household budgets needed to estimate how income changes within the experimental site may be affecting housing expenditures; to supplement the building and landlord surveys with additional information bearing on changes in the neighborhood and in the respondents' housing; and to
learn how the supply responses of landlords are conditioned by tenant characteristics and attitudes and how tenants respond to housing improvements and rent increases. We are especially interested in tenant turnover and its relationship to housing characteristics and management policies, and in patterns of household mobility after the commencement of the allowance program.

An important feature of the panel survey program described above is the opportunity it provides for linking the housing characteristics, landlord characteristics, and tenant characteristics of individual properties at each survey date; and for following these linked relationships over time. Such microdata, with both cross-sectional and longitudinal dimensions, are extremely rare in social science research; we expect them to be useful for analysis both of housing allowance issues and of more general questions relating to the dynamics of local housing markets.

In addition to these annual surveys of residential buildings, landlords, tenants, and homeowners, we plan a less frequent schedule of neighborhood surveys. At baseline and at 30-month intervals thereafter, fieldworkers will conduct a "windshield" survey of land use, housing characteristics, and public improvements throughout the entire site, recording the data separately for each block on every street. These data will be aggregated into neighborhood summaries, supplemented by information from public records about land use, traffic, public services, noise and air pollution, etc.

Survey records for individual properties will be coded by neighborhood, so they can be matched with the neighborhood data described above. Thus, we can analyze the influence of neighborhood characteristics on property values and on the responses of individual landlords, tenants, and homeowners to the allowance program.

**Tracking Allowance Recipients**

The disbursing agency for the housing allowance program will maintain continuous records on all participants in the program and on their
housing circumstances. Every six months, each recipient will be required
to report any changes in income or household composition. When an allow-
ance recipient moves, he must, of course, report his new address, but he
must also request an evaluation and certification of his new quarters.
For renters, the agency will also maintain a current record of the land-
lord's name and address and of the recipient's contract rent.

Thus, administrative requirements alone provide a substantial source
of data for following allowance recipients over time. From these com-
plete-count data, we can analyze changes in their housing character-
istics and housing expenditures and determine their patterns of residen-
tial mobility. In addition, many allowance recipients are expected to
turn up as respondents in our panel surveys, where they will be asked
about their experiences with the program and attitudes toward it.

Data on the pattern of residential location of allowance recipi-
ents will also feed into our analysis of landlord and tenant attitudes
and actions; we wish to examine their perceptions of neighborhood changes
that are possibly related to the allowance program in the light of our
direct knowledge of the extent and nature of these changes.

Other Surveys

We foresee the need for a number of special-purpose data-gathering
efforts during the course of the experiment, some of which may entail
small-scale surveys. For instance, we plan annual interviews with off-
cicers of the major institutions providing residential mortgage financing
within each of the sites, to learn from them as much as we can about
their policies and their perceptions of the allowance-stimulated market.
Firms writing property insurance may be surveyed in a similar manner.
We may undertake special inquiries among real-estate brokers, building-
trade contractors, and other participants in the local housing market.

Informal Monitoring

We are maintaining a full-time resident observer at each experi-
mental site for the duration of the monitoring period. His principal
assignment is to gather informal intelligence about community reactions
to the allowance program and to provide early warnings of possible
difficulties. The monitor will spend much of his time on the street and in attending meetings of civic and other local interest groups, reading local newspapers, and following events in City Hall.

Provided with technical support and staff assistance, he may also be asked to conduct some of the less formal small-scale surveys described above, or to search out local data from public records or other sources that bear on issues of experimental interest.

Termination of the Experiment

Although the allowance program will run for ten years, we believe that the information returns to the experiment will drop off sharply in the latter part of that period. The ten-year program commitment is needed to provide stable expectations. Program participants must know that their budgetary resources will be augmented for a long time if they are to commit their families to a higher level of housing consumption, which may require a lease at higher rent, a change of residence, or a change from rental to ownership tenure. The suppliers of housing must believe that the housing demand stimulated by the allowance program will last long enough to provide a continuing market for housing at rents that will amortize capital improvements.

If these expectations are provided by a ten-year program commitment, we believe that most of the dynamics of market response and realignment will have become evident at the end of five years, and the apparatus for monitoring the experiment can be dismantled. The allowance program can then be turned over to local control for continued operation under HUD funding.
III. THE EXPERIMENTAL HOUSING ALLOWANCE PROGRAM

The general purpose of the Supply Experiment is to provide information about the probable effects of a national housing allowance program. As outlined in Sec. II, our strategy for obtaining this information is to mount an experimental allowance program in each of two small metropolitan areas, matching on a geographically small scale the essential features of a national program.

Since a national housing allowance program does not exist, we must in many respects invent the model that we propose to copy in the Supply Experiment. However, there seems to be a consensus on the basic features of a national housing allowance program that distinguish it from existing methods for delivering housing assistance to households with low to moderate incomes and which, taken together, form a coherent alternative to these methods. Thus, we postulate the following essential features of the hypothetical national program to be emulated in our experimental program:

1. The purpose of the program is to enable and persuade households with low to moderate incomes to live in housing that meets specifiable minimum standards of health, safety, and decency for family life. In general, these standards can be met by a well-maintained older housing unit whose size is appropriate for the number of persons in a recipient's household.

2. The housing allowance strategy for attaining this purpose entails direct financial assistance to those who are judged unable to afford the market price of housing that meets these standards. Unlike the case with existing programs, enrollment is not limited to a predetermined number of "places" but is open to all who meet the personal and financial criteria for eligibility.

3. This assistance will be in some way earmarked for housing expenditures. Although the amount of assistance must take
into account the recipient's ability to pay for housing, housing allowances are not intended as general budgetary supplements.

4. Having provided the necessary purchasing power to participating households, the administering agency will limit its intervention in the process of housing choice to nondirective counseling; and in the relationships between tenants and landlords to the minimum consistent with fair housing laws and with the agency's accountability for public funds. It is assumed that a recipient will work through ordinary market channels to find acceptable housing and that he is capable of negotiating on his own behalf concerning rent and conditions of occupancy. The administering agency will have neither a current nor a contingent obligation to the seller of housing services.

Working within these principles, members of Rand's staff developed a model for a national housing allowance program that included specific eligibility criteria, an allowance formula, a method of payment, and earmarking provisions.* For the Supply Experiment, Rand proposed a modified version of that model. The modifications reflect in part the local nature of the experimental program and in part specific experimental needs not present in a national program. More importantly, they reflected constraints imposed by existing legislation and administrative regulations on the use of HUD funds for housing allowances.

We hasten to add that neither our model for a national program nor the modified version proposed by us for the Supply Experiment is uniquely consistent with the four principles cited above. Within their framework, other variants are possible. A number of such variants will be tried in the Demand and Administrative Agency experiments. Our recommendations reflected our own judgments on many details of design whose programmatic virtues are, in the absence of experimental evidence, arguable.

HUD accepted a number of important features of our proposal: the use of income, family size, and the local cost of standard housing as the principal factors determining need for assistance; assistance to both renters and homeowners who qualify as needy; direct payments to program participants rather than to their landlords or their mortgage holders; a housing-quality standard for allowance recipients as the principal means of earmarking; portability of allowances within the boundaries of the experimental site; and minimization of direct relationships between the administering agency and landlords whose tenants are allowance recipients.

However, the decision to fund the experimental program under the provisions of Sec. 23 of the U.S. Housing Act of 1937 entailed acceptance of program standards embodied in that law which are, in our view, sub-optimal. These include a specific method of income accounting and a specific formula for determining the amount of allowance payments, neither of which seems to us to take adequate account of the different budgetary problems of households of different sizes or with different sources of income.*

In the following pages, therefore, we describe an experimental housing allowance program that is a compromise between what would be optimal and what appears possible under existing constraints. Overall, we are satisfied that the outcome is consistent with experimental needs.

---

*For a systematic analysis and comparison of the properties of alternative housing allowance formulas and earmarking provisions, their effects on the recipients' housing choices and related behavior, and comparable estimates of allowance benefits, see Ira S. Lowry, Mark Ott, and Charles W. Noland, Housing Allowances and Housing Market Behavior, The Rand Corporation, WN-8028-HUD, January 1973.
GENERAL PROGRAM STANDARDS

The structure of our experimental housing allowance program is embodied in program standards of four types: those relating to eligibility for assistance, those that determine each participant's allowance entitlement, special conditions governing receipt or use of allowances, and commitments as to the duration of allowance entitlement. Below, we specify standards of each type, distinguishing those that reflect allowance-policy decisions, those that must be added because of the experimental nature of the program, and those that reflect legislative constraints on the experimental program.

Eligibility for Assistance

The basic principle of eligibility under a national housing allowance program is that assistance should be available to all households whose income from other sources does not enable them to afford the market price of housing that meets a specified standard of adequacy. We interpret this principle to mean that eligibility is independent of tenure, prior expenditures for housing, or occupancy of a particular housing unit. Rather, it depends on a comparison of household income with the market price of adequate housing, taking into account nonhousing consumption needs in calculating a household's ability to contribute toward its own housing expenses.

Income Limits for Eligibility. Following requirements of Sec. 23, the income limit for enrollment in the experimental housing allowance program is of the following form:

\[ Y_a = \bar{H}^* - \hat{C}^* \]  

(3.1)

where \( Y_a \) = maximum annual adjusted income for an eligible household of \( n \) persons; and

\( \bar{H}^* \) = standard annual cost (including utilities) of housing that meets specified quality standards and whose size is adequate for \( n \) persons.

Once enrolled, a household may continue to participate so long as its income is below \( \bar{H}^* \); the deductible $480 is an administrative convenience.
designed to avoid enrollment of households whose allowance entitlement would be less than $10 per month.

Income Accounting. Section 23, as interpreted by HUD, defines a household's total income as total recurring income received from all sources by the head of the household and spouse, and by each additional household member who is 18 years of age or older (unless that person is a full-time student). Most transfer payments are included; those specifically excluded are food stamp benefits, educational assistance, combat pay, and relocation assistance.

To arrive at adjusted income for program purposes, the following deductions from total income are mandated: 5 percent of total income for households whose head and spouse are both under 62 years of age, or 10 percent for households with older heads; extraordinary medical expenses not otherwise compensated; unusual occupational expenses; costs of care for children or invalids when necessary to the employment of the household head or spouse; $300 for each dependent other than the head and spouse; $300 for each nondependent secondary wage earner; and amounts paid for alimony or child support.

The one important innovation in Sec. 23 income accounting that was approved for the Supply Experiment applies to households that hold assets (specifically, real property) that do not yield a cash return. A percentage of net asset value is added annually to total income, representing the noncash flow of benefits derived from the use and

---

We would have preferred to relate eligibility (and the amount of allowance entitlement) to disposable income rather than adjusted income, as defined by Sec. 23. Generally, we would define disposable income as total income less federal, state, and local income taxes, compulsory social insurance payments, extraordinary medical expenses, and work-related expenses of employed members of the household.

Existing federal programs of housing assistance all express income limits in terms of adjusted income; the adjustments vary from program to program, usually providing deductions for minor children or excluding their earnings, and in some cases allowing deduction of social security taxes and union dues. In no case do the adjustments go far enough to equalize the disparities in disposable income between households dependent on current earnings (subject to income and social security taxes and accompanied by unavoidable work-related expenses) and those dependent on pensions or transfer payments (generally non-taxable). Households supported by the employment of one or more members are invariably penalized.
enjoyment of the asset. This rule helps to equalize the treatment of renters and homeowners; renters generally hold their assets in a form (e.g., a savings account) that yields an annual cash flow, whereas homeowners accumulate equities in their homes, whose benefits are realized as noncash flows of housing services.

The Standard Cost of Adequate Housing. The other variable in Eq. (3.1) is $R^*$, the standard cost of adequate housing. Initial values for $R^*$ at each experimental site were based on housing-market data gathered prior to the opening of enrollment. In the course of screening residential properties for inclusion in the baseline sample, we surveyed the occupants of nearly 10,000 housing units at each site. For each rental unit, we inquired about current contract rent, division of responsibility for utility bills, number of rooms and bedrooms, and a series of items bearing on housing quality.

We used these data to estimate gross-rent distributions for each size of housing unit, and to classify units according to their quality (passing or failing a minimum standard). Then, we agreed with HUD on a schedule of gross rents that would enable program participants generally to afford adequate rental housing in the local market, the amounts varying with household size. The same value of $R^*$ applies to all participating households of a given size, whether they are renters or homeowners.

Site-Specific Program Standards. Table 3.1 shows the values initially selected in each experimental site for the standard cost of adequate housing, by size of household; and the corresponding income limits for enrollment in the program. The values differ between sites for two reasons. First, the sites were selected in part because of differences in their housing markets, reflected in the market rents underlying our schedules of values for $R^*$. Second, our screening survey was conducted in Site II nearly a year later than in Site I, so that the market data for the two sites are not directly comparable.

**Source:** Calculated by EA staff from HUD-approved program standards.

**Notes:** Adjusted Income Limit = " - 2.

All cash income and imputed income from assets, after exclusions and deductions provided for by program rules, limit for continued participation is $200 more than the income shown.

Estimated total is the corresponding full adjusted income for a typical household of that size. Among single persons, only those over 65 years of age are eligible. Households of two or more persons are assumed to be headed by a married couple both under 60 years of age. It is assumed that there is only one employed household member; that all other household members are dependents; and that there were no extraordinary medical or work-related expenses.

Based on local housing-market data for September 1971.

Based on local housing-market data for July and August 1974.
We would expect a national program to set values for \( R^* \) to reflect local or regional differences in housing costs, though perhaps not by the procedures described above; over time, we would expect these values to be adjusted to reflect changes in the market price of housing. For the experimental program, the values of \( R^* \) were set in advance of the opening of enrollment; neither HUD nor the local agency administering the allowance \( * \) will be committed to adjusting these values in the event of price changes, although this may be done at some point during the life of the program if it appears that background inflation, unrelated to the allowance program, is unduly depreciating the value of scheduled allowances.

**Asset Limits for Eligibility.** Independently of the income limits described above, HUD has set a limit on net assets of $20,000 for a household whose head and spouse are both under 62 years of age, and $32,500 for households headed by older persons.

These limits are well above those of most federal housing assistance programs, being designed to permit homeowners to participate in the experimental program. Given the provision described above for imputing income to homeowners' equities, the asset limit will only rarely be a more binding constraint than the income limit, and we do not think that its inclusion in program standards will significantly change the population served by the program.

**Definition of Household.** For purposes of determining eligibility and allowance entitlement, a household is defined as one person living alone, or two or more persons living together, all of whom contribute jointly to housing expenses or else are legally dependent on a member who does contribute. Ordinarily, a household consists of persons related by blood or marriage, but unrelated individuals may be included, provided that they depend on the head of the household for at least half of their support and that their income is counted in the amount used to

*The latter is a Housing Allowance Office established at each experimental site. Its structure and functions are briefly described later in this section.*
determine eligibility. An unrelated lodger who pays rent to the head of the household is not considered a household member, but may separately be eligible for assistance.

The legislative authority under which the experimental program will be funded requires some qualification of this definition. Persons under age 62 who live alone will be ineligible for assistance unless they are handicapped or residentially displaced by a natural disaster or by actions taken under specified public programs such as urban renewal.

Residency Requirement. In a national housing allowance program, there would be no residency requirement. Housing allowances would be available across the country, and program participants who moved could reestablish eligibility in their new place of residence, subject to the standards in effect there.

For the experimental program, special rules must be devised to forestall disruption of the local housing markets owing to movement into the experimental sites by low-income households eager to share in allowance benefits, without unconstitutional discrimination against "normal" movers.

Our solution to this problem has two parts. First, applications for enrollment in the experimental program will be accepted only from households already residing within the program's jurisdiction, and no determination of eligibility will be made for nonresidents. Second, all applications from households residing within the program's jurisdiction on the date the program was funded will be processed before applications from those who subsequently move into the jurisdiction. Since the number of households who may participate in each site is limited by an annual contributions contract between HUD and a local housing authority, there is no guarantee that new residents will ever be enrolled.

Once enrolled in the experimental program, a household will continue to be eligible for assistance as long as its income does not exceed the limit for its size and as long as it continues to live within the boundaries of the experimental site. Outmigrants will lose their allowances for the period of their absence but will be able to reenroll upon returning to the site if they are still otherwise eligible. A
household meeting the residency requirement need not apply at the inception of the program; if it meets all other requirements, it may be admitted to the program at any time.

These rules provide the Housing Allowance Office (HAO) with considerable control over the size of the program and should lead to a relatively stable flow of allowance payments throughout its term. Attrition through outmigration and death of recipients should be approximately offset by natural increase in the membership of recipient households and by enrollment of households who become eligible as they withdraw from the labor force because of age or illness.

Amount of Assistance

The size of the allowance to which a household is entitled will be calculated by means of a formula that takes into account differences in housing needs and other consumption requirements between households of different sizes, and which reflects the current relationship between a household's adjusted income and the cost of living, including the cost of adequate housing. It is designed so as to fit into the existing mosaic of public assistance programs (social security, unemployment compensation, welfare) without providing windfalls for their beneficiaries, and to adapt housing assistance payments automatically to future changes in benefits provided by these other assistance programs.

The formula provides for housing assistance equal to the difference between the standard cost of adequate housing (varying with household size) and a specified percentage of the adjusted income of the assisted household. It is thus a member of the "housing gap" family of allowance formulas whose general form is

\[ A = \omega Y^* - \beta Y_A, \]  \hspace{1cm} (3.2)

where \( A \) = amount of allowance entitlement;
\( Y^* \) = standard cost of adequate housing;
\( Y_A \) = adjusted income from other sources; and \( \omega \) and \( \beta \) = policy parameters.

See Lowry, Ott, and Nelson, *Housing Allowances: An Economic Perspective*, Sec. II.
For the Supply Experiment, \( \alpha = 1 \) and \( \beta = .25 \), so that Eq. (3.2) reduces to

\[ a = r^* + .25Y_G. \]  
(3.3)

In principle, at least, a household with no income from other sources would be entitled to an allowance of \( r^* \). Such an extreme case is unlikely inasmuch as all states provide public assistance to nearly all individuals and families who are without other means of support; and in calculating allowance entitlement, unemployment compensation and welfare payments will be counted as income.

As adjusted income increases from zero under this formula, the amount of the allowance entitlement decreases at the rate of 25 cents per dollar of additional income. When adjusted income reaches \( 2r^* \), the allowance entitlement drops to zero; thus, as noted earlier, \( Y_G = 4r^* \) is the upper income limit for continuing eligibility.

Although a household's allowance "entitlement" is independent of its actual housing expenses, HUD has placed an additional restriction on allowance payments. They may not exceed actual housing expenses for the recipient's current residence. This provision is intended by HUD to restrict the recipient's use of program benefits for nonhousing purposes. However, it also may affect the use of program benefits for housing purposes. Thus, a participant whose current housing meets program standards may find it advantageous to move to more expensive quarters if doing so would enable him to claim a larger allowance payment. Since allowance entitlement is normally only a fraction of \( r^* \) and since \( r^* \) reflects local housing costs, allowance entitlement should only rarely be more than actual housing expenses.

---

* Other values of \( \beta \) are to be tested in the Demand Experiment; although \( \alpha \) will not be explicitly varied from unity in the Demand Experiment, the procedures used there to determine \( r^* \) seem to be the equivalent of setting \( \alpha = 1 \) for \( r^* \) as defined above.

** Over the full range of eligibility, the formula thus imposes a "tax" on income from other sources, the amount of the tax depending on the sources of other income. See Lowry, Ott, and Noland, Housing Allowances and Household Behavior, pp. 81-92 and Appendix C, for analysis of the implied marginal tax rate on earned income under this and other allowance formulas.
As explained earlier, the standard cost of adequate housing, \( \tilde{c}^* \), has been determined for each size of household from data for each experimental site. To give the reader a general indication of the levels of allowance payments contemplated by this formula, we have prepared a schedule of allowance entitlements for each site based on the program standards just described (Table 3.2). For each size of household, the amount of the allowance decreases from \( \tilde{c}^* \) to zero as adjusted gross income rises from zero to \( \tilde{c}_a^* \). A glance at this schedule probably leaves an impression of higher average allowance payments than is actually the case, since the first few rows are for levels of incomes whose incidence in the population is low, and the last two columns are for household sizes whose incidence is also low. Experience in Site 1 during 1974 indicates an average annual payment of $700 to $800 per household.

Our analyses also indicate that the allowance schedules conform to constraints imposed by the legislative restrictions under which the experimental program is funded. The major legislative constraint is the Brooke Amendment, which limits the housing expenditure that may be required of an assisted household to 25 percent of its adjusted income. The rules of the experimental housing allowance program do not require any specific contribution by a participating household, but the federal contribution will amount to standard housing cost less 25 percent of the recipient's adjusted income.

Conditions of Assistance

To distinguish a housing allowance program from general income transfers, some method of earmarking allowances for housing expenditures is needed. While various methods are possible, all require the recipient either to spend at least a specified amount for housing or to occupy housing that meets specified standards of space and quality. Because of its more direct linkage to program objectives, we have chosen the latter course despite the greater administrative burden it entails.*

*See Lowry, Ott, and Noland, Housing Allowances and Household Behavior, Sec. V, for a discussion of alternative earmarking schemes and the incentives for housing expenditure, housing choices, and fraudulent practice that each brings into play.

</table>

SOURCE: Computed by HASE staff from program standards in Table 3.1.

NOTE: Allowance payments are limited to an amount equal to actual housing expenses in the current residence even though entitlement may be larger.

Applies only to households already enrolled. A household whose benefits under the allowance formula would be less than $120 annually is not eligible for enrollment.
Under the experimental allowance program, an applicant will be enrolled if his income and household size entitle him to benefits. However, actual payments will begin only when the enrollee is able to show that his housing meets certain standards for quality and condition of structure adapted from local and national model housing codes, and that it conforms to specified standards of minimum space per person. These standards are more elaborate than, but essentially the same as, the standards used to select local values for $R^*$, the market price of adequate housing at each experimental site. In general, well-maintained older housing will qualify if it has a bedroom for every two household members.

At each experimental site, certification of housing units for occupancy by allowance recipients will be accomplished by evaluations conducted by the HAO.* In some cases, the housing occupied at the time of enrollment may qualify. If it does not, the enrollee must improve the property if he is a homeowner, or if he is a renter, persuade the landlord to improve it; or in either case, he may move to housing that does meet the standard.

Because of the procedure used to determine $R^*$, we are assured that certifiable housing is generally available in the community for rents in the vicinity of $R^*$; and we presume that additional units can be brought up to the standard of certifiability and profitably marketed at rents or annual ownership costs in the same vicinity. (One of the purposes of the Supply Experiment is to test this presumption.) The allowance schedule is constructed to ensure that all enrollees, of whatever household size and income, can afford to spend $R^*$ for housing, combining the allowance with a fourth of nonallowance income. Thus, the quality standard compels enrollees to pay for adequate housing as a condition of receiving the allowance that enables them to do so.

This is not to say that program regulations will require any recipient to spend exactly or at least $R^*$. Within the market, certifiable

*For a national housing allowance program, we would not recommend such a special inspection system. Rather, we would recommend that any municipal jurisdiction's participation in the program be conditional on its adopting a model housing code and meeting specified standards of enforcement.
housing will vary in cost; some may find such housing at a rent or annual homeowner cost of less than \( R^* \), while others may pay more, perhaps for special features that they find attractive. Since the amount of the allowance does not vary with actual expenditures, there is an obvious incentive to seek the best bargain available that meets program standards of quality.

Once in a certified housing unit, an enrollee is entitled to allowance payments as long as the unit continues to meet program standards. Each such unit will be reevaluated annually at the instance of the HAO, although other events might lead to interim evaluation and decertification. After notifying the allowance recipient of decertification, the HAO will allow reasonable time for corrective action and recertification. If the dwelling is not brought into compliance with program standards by the end of that period, allowance payments will cease until either the unit is reevaluated and recertified or the enrollee moves to another unit.

If an enrollee moves, payments are suspended until his new residence has been certified; by requesting a premove evaluation of his prospective quarters, the enrollee can avoid any interruption of payments.

**Duration of Assistance**

Once approved and funded by the Congress, a national housing allowance program would presumably be regarded by the public as a permanent feature of local housing markets, even though it could be repealed by a subsequent Congress and even though its funding would require annual appropriations. This sense of permanence would have an important influence on the behavior of both allowance-eligibles and suppliers of housing services.

Without the expectation that allowance payments would continue for a long period of time, those eligible to participate in the program would, we think, hesitate to move, to alter their present housing arrangements, or to enter into financial commitments beyond their pre-allocation means. If landlords, developers, and speculative rehabilitators of residential property did not believe that the allowance-stimulated demand for housing services would persist for a long time,
they would be reluctant to commit themselves to capital improvements or long-term investments.

It thus becomes important to design the experimental allowance program so that it evokes the sense of permanence associated with a national program. The duration and firmness of program commitment needed is a matter of judgment. Allowance entitlement for enrollees in the Demand Experiment runs for three years; in the Administrative Agency Experiment, the term is two years. * To meet the needs of the Supply Experiment, we think a much longer term is needed.

To obtain better housing, those eligible for assistance may have to sign leases at higher rents than they could support without allowances, move to new quarters, undertake capital improvements on homes that they own, or shift from rental to ownership tenure with a long-term mortgage commitment. For renters, our judgment is that a five-year allowance commitment would yield nearly the same behavior as a ten-year commitment; longer leases are not likely and moving costs amortized over five years become insignificant relative to allowance benefits. For homeowners contemplating capital improvements, the critical issue is likely to be the need for a home-improvement loan to be amortized over five to ten years. For those considering a shift from rental tenure to ownership, an allowance commitment matching the required mortgage commitment in its duration seems appropriate both to properly influence expectations and to avoid placing HUD in the politically and ethically awkward situation of encouraging low-income households to assume obligations they cannot meet.

In the rental market, we think that the landlord's expectations are critical. Neither the experimental program nor a national housing allowance program offers the landlord any guarantee that he will benefit from the allowance payments. He will observe a general increase in low-income housing demand, a share of which he may be able to capture in competition with other landlords. The risks he is willing to take to

---

* In both cases, enrollees are promised special consideration for enrollment in other (nonexperimental) housing assistance programs that may be operating in their communities when the experimental allowance program terminates.
capture a share of this demand (benefiting from a higher occupancy rate or higher rents or both) clearly will depend on his perception of its durability. Whatever the mix of allowance recipients’ preferences between increased services and capital improvements, a short-term allowance commitment would bias a landlord’s response toward service improvements and toward less total increase in factor inputs.

We do not think that even a ten-year allowance commitment would create for landlords and speculative rehabilitators of residential property all of the expectations of a permanent program. Structural rehabilitation on the basis of 20-year mortgage financing is not uncommon; some federally subsidized rehabilitation mortgages have terms of 40 years. As we understand such investments, cash flow rather than equity accumulation is usually the dominant consideration—if not to the borrower, then to the lender. If so, every dollar increase in annual debt service must be matched by a dollar increase in expected annual revenue to provide a horizon-neutral investment incentive.

Assume that with an unlimited horizon for the allowance-stimulated demand increase, a landlord could get 21-year financing for rehabilitation at 8 percent and he concluded that such an investment would be marginally profitable. With a ten-year or five-year allowance commitment, the investment would be less interesting to both the landlord and the lender. To amortize the investment over ten years would require annual debt-service charges that are 1.5 times the charges for 21-year amortization; a five-year amortization schedule raises the annual charge to 2.5 times the 21-year charge.*

If we also assume a balanced program of housing improvement with proportional increases in all inputs, over a typical initial mix of inputs, these alternative horizons yield different price elasticities of supply. If the 21-year horizon has an elasticity of unity, we estimate that the ten-year horizon would have an elasticity of .96 and

*The computations leading to these conclusions can be found in Lowry, Rydell, and de Ferranti, Testing the Supply Response to Housing Allowances, pp. 55-56. Also see C. Peter Rydell, The Landlord Rehabilitation Model: A Computer Based Method of Evaluating the Financial Viability of Alternative Treatments for Problem Buildings, The Rand Corporation, R-4477, October 1970.
that the five-year horizon would have an elasticity of .90. Different but reasonable assumptions would yield slightly different answers, but we believe that these illustrative calculations reflect as well as any others the probable biases in supply responsiveness associated with short-term allowance commitments. In our judgment, the 4-percent bias associated with a ten-year term would not seriously degrade the usefulness of our experimental findings, especially since the direction of bias is clear. The 10-percent bias associated with a five-year commitment is, we think, larger than is consistent with experimental purposes and credibility.

These considerations lead us to believe that a ten-year program commitment would be adequate to create an appropriate climate of expectations among landlords, renters, and homeowners. However, even a ten-year commitment is less than satisfactory as an approximation of the effects of a permanent national program on the choices of renters contemplating buying a home.

Although HUD and Rand at one time considered special provisions for home purchasers, extending their allowance commitments for the lives of their mortgages, we did not finally urge that this be done. For one thing, it would distort tenure choices by providing greater total benefits to home purchasers than to others with equal need for assistance. For another, allowance schedules were designed to support the full costs of well-maintained older housing; we would not expect program participants, even with "permanent" entitlement, to be able to afford new single-family houses. Finally, we could find no satisfactory legislative vehicle for a 20- to 30-year commitment of assistance in a form approximating a housing allowance. Thus, we concluded that home purchasers and mortgage lenders should be asked to base their decisions on a maximum commitment of ten years of assistance.

HUD has provided the commitment we sought in the form of a ten-year annual contributions contract with a local housing authority in each experimental site, the terms of which are explained below. Here we note that what is guaranteed by this contract is continuation of the program, not payments to any specific household. A household enrolled in the program may lose its allowance entitlement because of a change
in income or household size or because it leaves the program's jurisdiction; and its payments may be suspended because its housing falls below program standards.

In the event that unforeseen circumstances require the experimental aspects of the housing allowance program to be terminated sooner than is now planned, the HAO will nonetheless continue to provide the promised assistance for the full ten-year period.

PROGRAM ADMINISTRATION

The experimental housing allowance programs at each site are funded under Sec. 23 of the U.S. Housing Act of 1937, the "leased public housing program." Special administrative regulations promulgated by HUD enabled modification of the usual form of this program to fit the requirements of the Supply Experiment.

Ordinarily, housing programs funded under Sec. 23 are administered by a duly constituted local housing authority (LHA), and the existence of a suitable public agency is a legislative requirement for Sec. 23 assistance. Local housing authorities, either municipal or countywide in jurisdiction, existed in each metropolitan area considered as a site for the Supply Experiment. However, these bodies administered programs that were small relative to the anticipated size of the experimental allowance programs.

In order to provide administrative capacity for rapid enrollment in and subsequent management of the large-scale experimental program, we established a nonprofit corporation at each site, called a Housing Allowance Office. HUD has funded the allowance program by entering into an annual contributions contract with the appropriate LHA. The LHA in turn contracts with the HAO for the latter to administer the program and to disburse the funds.

Each HAO is governed by a board of trustees whose members are appointed by an officer of The Rand Corporation. From the beginning, the board includes both Rand-affiliated members and representatives of the local community; Rand members, initially a majority, will be replaced by community members when the experiment terminates (about

* See "Program Funding and Forms of Payment," below.
halfway through the term of the allowance program; thereafter, control of the HAO will be entirely in the hands of community representatives.

Soon after each HAO was established, its board of trustees appointed a director for the HAO, who is responsible for staffing the office and administering the experimental allowance program. The HAO's functions include provision of public information about the allowance program, outreach and eligibility screening, certification and recertification of eligibility, enrollment of eligibles, determination of allowance entitlement, provision of housing information and equal opportunities counseling to enrollees, disbursement of allowance payments, evaluation and certification of housing units occupied by recipients, and responding to grievances submitted by program applicants or participants.

Technical support and assistance in staffing is provided to the HAO at each site by Rand. Our general objectives are (a) to create organizations capable of managing the heavy workload of the experimental program, (b) to ensure that administrative procedures are efficient and that they conform to experimental needs both substantively and with respect to recordkeeping, and (c) to build an institution with the staff resources needed to operate the allowance program after Rand's direct involvement terminates.

For the reasons explained in Sec. II, establishment of the HAO in Site II lagged the corresponding event in Site I by about nine months, and program jurisdiction in Site II is initially limited to the central city rather than incorporating the entire experimental site. Otherwise, the two HAOS are as similar in organization and administrative procedures as local circumstances will permit.

**PROGRAM FUNDING AND FORMS OF PAYMENT**

Presumably, a national housing allowance program would operate under specific legislation authorizing expenditure of appropriated funds as needed to achieve program purposes. Typically, such legislation allows considerable administrative discretion in program design.

*See the subsection on site selection.
The Supply Experiment lacked such freedom. Because the experimental allowance program in each site had to be large and long-lasting to fulfill experimental requirements, it could not be sustained out of HUD's housing research budget. Instead, HUD and Rand collaborated in finding an existing housing assistance program that could be adapted to a housing allowance format.

Although a variety of possibilities were explored, our joint attention eventually focused on Sec. 23 of the U.S. Housing Act of 1937, the "leased public housing program."

Under this legislation, HUD normally entered into an annual contributions contract with an LHA, guaranteeing funds to provide housing assistance for a specified number of households living in privately owned housing units. Ordinarily, the LHA searched the local housing market for appropriate units, leasing them from their owners at a negotiated rent (presumably fair market rent) for a minimum term of one year; sometimes, advance leasing commitments were offered to developers for units yet to be built or rehabilitated. Then, acting as landlord, the LHA sublet these units to eligible households at rents below the market, usually determined by comparison with rent schedules in public housing units owned by the LHA. The amount of the subsidy, covered by the annual contributions contract, was the difference between the lease rent and the sublease rent on each unit. The basic contractual relationships are shown in Fig. 3.1.

Fig. 3.1 – Standard contractual relationships: Sec. 23 leased housing program

The households subsidized under this program were selected by the LHA from among those who applied for the limited number of available "places." Income limits for enrollment were determined by the LHA,
subject to HUD approval; and like the participant's rent obligation, they usually followed the precedent of the local public housing program. Under the 1969 Brooke Amendment, no participating household could be required to pay more than 25 percent of its adjusted income as contract rent to the LHA; special federal contributions were available as supplementary subsidies for cases in which the permissible tenant contribution was less than the scheduled sublease rent.

Special HUD regulations governing the use of Sec. 23 funds in the Experimental Housing Allowance Program made it possible to alter these procedures in ways that yield a close approximation to our national model for a housing allowance program. In the Supply Experiment, HUD has entered into an annual contributions contract with an LHA in each experimental site. The LHA in turn has contracted with the HAO, described above, for the latter to administer the experimental program, passing through to it the funds obtained under the annual contributions contract. Both contracts run for ten years.

Limits on Program Size and Cost

The annual contributions contract (ACC) thus provides the necessary long-term program guarantees. However, this form of funding raised another problem. To test the limits of program participation in a national program, we wanted an open enrollment policy for our experimental program. In other words, we wanted to be able to enroll all eligible applicants rather than filling a limited number of "places" in the program. An ACC, however, contains ceilings both on the number of households that may be assisted at any given time and on annual federal contributions.

The solution was to seek an ACC for each site that would cover our best prior estimates of the number of eligible households that would seek assistance and the amount of federal contributions needed to supply assistance to them. (The ACC covers both payments to participating households and the expenses of program administration.) At the time these estimates were needed, only 1970 census data on household sizes and incomes and local housing costs were available, and detailed rules for determining eligibility and allowance entitlement were still being formulated.
After a series of statistical exercises, Rand provided HUD with estimates of program size and cost under various contingencies, and agreed to terms of the ACC for each site.* In Site I, the ACC provides for a maximum annual contribution of $9.2 million to support allowance payments for up to 6,096 households in Brown County at any given time.

In Site II, the experimental program is presently limited to the city of South Bend, but the ACC provides for its possible extension to the remainder of St. Joseph County. The maximum annual contribution is $17.5 million and maximum enrollment is 9,638 households.**

Data gathered in our field surveys subsequent to decisions on ACC terms generally confirm our earlier estimates of the numbers of eligible households in each site, roughly twice as many as are covered by the ACCs.*** Nonetheless, we judge from the experience of other federal transfer programs that the ACCs will cover all those who actually apply, enabling the HAOS to maintain an open enrollment posture at least as long as is needed to provide the basis for reliable estimates of long-run participation rates.

Assistance to Renters

In the experimental allowance program, funds needed to provide assistance to renter households are provided under the authority of Sec. 23, but contractual relationships, shown in Fig. 3.2, differ from the usual arrangements.

Applying standards described earlier in this section, the HAO enrolls eligible renter households and calculates the amount of allowance to which each is entitled. The relationship between the HAO and the

---

* For examples, see Barbara M. Woodfill, Tiina Repnow, and Ira S. Lowry, *Estimates of Eligibility, Enrollment, and Allowance Payments in Green Bay and Saginaw: 1974 and 1975*, The Rand Corporation, W-8439-HUD, September 1973. (At that time, Saginaw was the leading candidate for Site II. Similar estimates were later prepared for St. Joseph County when it was selected as the second experimental site.)

** The difference in the number of households coverable in the two sites reflects mostly a corresponding difference in population size. In 1970, Site II had nearly 76,000 households, as against 44,000 in Site I. Thus, in both cases, the ACC provides coverage for about 13 percent of all households in the experimental site.

*** See Tables 3.4 and 3.5, below.
enrollee is formalized by a participation agreement which ensures the enrollee of his allowance entitlement once he occupies a certified housing unit. The enrollee then applies for certification either of his present housing or of some other unit. When the unit has been evaluated and certified, the enrollee negotiates a lease with its owner; the HAO is not a party to this lease. When a copy of the lease is submitted to the HAO and approved as to form, the HAO begins to issue monthly checks to the enrollee in the amount of his monthly allowance entitlement or of his actual housing expenses, whichever is less. The checks are fully negotiable by the enrollee; he may cash them or endorse them to his landlord as he chooses. Normally, he must supplement his housing allowance with some amount of nonallowance income in order to make up the total contract rent of his housing unit and pay his utility bills.

Although contract rent, as specified in the lease agreement, is reported to the HAO, its amount is subject only to agreement between the landlord and the enrollee. The latter is fully responsible for meeting his obligations under the lease agreement, and the landlord has no recourse to the HAO in the event of default by his tenant. Except that the landlord must obtain prior approval from the HAO to evict a tenant, normal civil procedures apply to the settlement of landlord-tenant disputes.

*The lease agreement must have a nominal term of a year, although it can provide for earlier termination by either party. The existence of such a lease is a requirement for assistance under Sec. 23."
The HAO will continue to provide monthly payments to each enrolled renter household for the duration of the experiment, provided that the recipient and the housing unit continue to meet all program requirements. The amount of the payment may change to reflect changes in the enrollee's income or household size, which are reviewed semiannually by the HAO. It is also possible that market information may lead at some time to changes in the HUD-approved schedule of the standard cost of adequate housing, which would change the amounts of allowance entitlement for all enrollees.

The enrollee's housing unit is reevaluated annually by the HAO. If it falls below minimum standards of adequacy, payments to the enrollee are suspended unless appropriate improvements are made or until the enrollee moves to another, certifiable unit. Although the HAO will review with the landlord its reasons for decertifying a unit, it is the enrollee's responsibility to arrange with the landlord for any needed repairs. Before suspending payments, the HAO allows a reasonable period for repairs to be made and for the unit to be recertified.

Subject only to his lease agreement, an enrolled renter may move within the program's jurisdiction at any time without affecting his eligibility for assistance. To avoid suspension of payments, however, he must arrange prior to a move for an HAO evaluation and certification of his new residence and submit a lease agreement with his new landlord.

Assistance to Homeowners

Current estimates for our experimental sites indicate that about 60 percent of all households eligible for assistance under the income standards approved for the program are homeowners.* While we were at first surprised by this finding, we now think it would also hold true

* See Tables 3.4, 3.5, and 3.6, below. These estimates are crude because, among other reasons, imputed income from homeowners' equities is included in total income for program purposes; and systematic data on homeowner equities were not then available for the populations of the experimental sites. Even without including imputed income, we found that the average allowance entitlement of eligible homeowners was less than for eligible renters, reflecting generally higher incomes for homeowners in relation to household size.
for the nation as a whole. Apparently, low-income households are predominantly renters only in large cities.

Public discussion of the housing allowance concept has for the most part assumed that the beneficiaries would be renters, perhaps reflecting the customary focus on big-city housing problems. However, our field visits to the small metropolitan areas under consideration as experimental sites revealed as much public concern there for the housing and budgetary problems of low-income homeowners as for those of renters. Our own calculations, as yet crude, support the view that homeownership is by no means evidence of lack of need for housing assistance.

Consequently, we thought it was important both in terms of fairness and program purposes to provide assistance to homeowners as part of the experimental allowance program. It also seemed essential to do so in order to provide an appropriately brisk stimulus to the local housing markets of our two experimental sites. Finally, we wished to avoid the confusing consequences of a general incentive for otherwise eligible homeowners to sell their homes in order to qualify under the rental program described above.

At an early stage of planning for the Supply Experiment, HUD and Rand agreed on the importance of homeowner assistance. The practical problem was to find an appropriate legislative authorization for funding such a program. After examining and discarding a number of possibilities, we focused on Sec. 23 as the most suitable vehicle. Following the precedent of a program operated under Sec. 23 by the Housing Authority of Contra Costa County, California, we proposed a lease-leaseback relationship between the HAO and the homeowner that appeared to satisfy the statutory requirements of Sec. 23 and at the same time would enable the HAO to assist homeowners on nearly the same terms as it assisted renters. The arrangement was finally approved by HUD in February 1974.

Figure 3.3 shows the basic contractual relationships. When a homeowner applies for enrollment in the allowance program, his residence is evaluated by the HAO to determine whether it meets program standards. Once the housing unit has been certified, the homeowner executes a
Fig. 3.3 – Special contractual relationships: Sec. 23 experimental housing allowance program for homeowners

participation agreement and, at the same time, leases his home to the HAO for the duration of his participation in the program. The consideration under this lease is the program benefits to which the lessor then becomes entitled. The HAO in turn executes a sublease with the homeowner as lessee. The consideration under this sublease is the homeowner's agreement to meet his program obligations.

It is important to note that this arrangement does not entail transfer of title or the creation of any new lien on the property, nor does it require refinancing of any existing mortgages. The homeowner may terminate both leases at any time by simply giving notice to the HAO that he is terminating his participation in the program. On the other hand, neither the LHA nor the HAO has any contingent liability in the event of mortgage default or uninsured damage to the property. The homeowner is responsible for all taxes and legal assessments against the property and for all expenses incurred for its maintenance, operation, repair, or improvement.

As it does for renter participants, the HAO will review the incomes and household sizes of homeowner participants semiannually, adjusting allowance entitlement as appropriate. Allowance entitlement is based on the same schedule of standard housing costs that applies to renters; likewise, the maximum payment is the smaller of the calculated allowance entitlement or actual housing expenses. However, for homeowners, the latter constraint is more likely to be binding than it is for renters.

For renters, actual housing expenses are defined as the sum of contract rent plus the estimated cost of any tenant-paid utilities...
electricity, water and sewage charges, and trash collection).* For homeowners, actual expenses are defined to include mortgage interest payments, real-estate taxes, insurance, and estimated maintenance and operating costs. Over Rand's objections, HUD declined to allow the opportunity cost of the homeowner's equity as an annual housing expense; thus a homeowner whose property is heavily mortgaged is considered by the HAO to have greater annual housing expenses than one who owns his home free and clear, even though the true costs may be identical in the two cases.** We do not yet know how often this restricted view of housing expenses will affect allowance payments, but in principle it provides an incentive for homeowner participants to mortgage their homes and invest the proceeds elsewhere.

As with renter participants, the HAO will evaluate the housing unit of a homeowner at the time of enrollment and annually thereafter. Allowance payments will not commence until the unit is certified, and they will be suspended if a subsequent evaluation reveals unacceptable conditions. The owner participant is solely responsible for maintaining the unit in certifiable condition and for arranging any loans he may need to finance repairs or improvements. Presumably, his certificate of enrollment in the program and entitlement to monthly assistance payments will be of some value to a prospective lender as evidence of creditworthiness.

Assistance to Home Purchasers

As explained earlier, Rand and HUD at one time contemplated special arrangements for assistance to home purchasers, but were unable to find a format that both met experimental needs and could be funded under existing laws.

Consequently, the experimental housing allowance program makes no special provisions for an eligible household that wants to purchase a

* Landlord and tenant responsibilities for utility charges are specified in the lease agreement. Amounts are estimated by the HAO from a standard schedule.

** Note that imputed income to a homeowner's equity is counted as an element of total income in determining allowance entitlement.
home. Such a household may enroll in the program and the HAO will provide it with a statement of the amount of its allowance entitlement. When the prospective home buyer locates a suitable house, the HAO will evaluate it on request, to determine whether it meets program standards. Thus, prior to any commitment by the home buyer, he can determine whether he is entitled to an allowance, what the amount of the allowance will be for the following six months, and whether the home he has selected will qualify him to receive payments.

This information should help him to make a responsible decision and also to secure mortgage financing for his purchase. Although the maximum period of allowance entitlement is ten years rather than the term of a typical mortgage, the lender should regard allowance entitlement favorably in assessing the household's creditworthiness and may even think of the HAO's annual reevaluation of the property as beneficial in protecting the collateral for the loan. It is worth noting that allowance entitlement is in some ways superior to ordinary income as evidence of long-term ability to meet monthly payments: If non-allowance income decreases, allowance income will automatically be increased, compensating for a fourth of the lost income.

However, the HAO itself offers no guarantees to a mortgage lender on behalf of a program participant, and we are not sure how lending institutions will adapt their tests of creditworthiness to take account of allowance entitlement. In any event, our standards for allowance entitlement generally imply that homes affordable by allowance recipients would at best be well-maintained older housing, a limitation that we expect would be enforced by private mortgage lenders: They would limit the loan to an amount the borrower was clearly able to repay from his allowance-augmented income.* We do not suppose that all allowance-eligible households would be able to obtain mortgage credit of any kind;

* Especially in Site II, there are many small frame houses 30 to 50 years of age on the market at prices that program participants could afford despite current high mortgage interest rates. Most of these would probably need some repair or modernization to meet HAO standards. One possible market response to the experimental allowance program is speculative rehabilitation of such properties for sale to program participants, provided that mortgage funds are available.
those with very low incomes, especially, would have to settle for rental tenure.

**Phasing Enrollment**

For a national housing allowance program, a major consideration governing the pace of enrollment and initial disbursement of allowance payments is certain to be administrative efficiency in staffing and managing a large-scale but decentralized program. Depending on the findings of the Supply Experiment, an additional consideration might be the desire to meter enrollment over time so as to avoid overburdening an unresponsive market with excess housing demand.

Although much can be learned from the Supply Experiment about the administrative problems of a national housing allowance program, the experiment is not intended, as is the Administrative Agency Experiment, to focus on these problems. In mounting the experimental allowance program, we have instead considered primarily the need to produce the appropriate climate of market expectations, deploying all the administrative resources we could muster to implement the allowance program smoothly and speedily. Certainly, we did not attempt to simulate the limitations as to quantity and quality of staff, availability of office equipment and supplies, etc., that would inevitably constrain the effectiveness and speed of implementation of a national program. While we cannot escape all such limitations, our primary consideration in phasing enrollment and disbursement has been the effects we wish to produce in the housing market.

Because the experiment is of limited duration (and its extension would be expensive) and also because experimental findings will be less pertinent to policymaking the longer they are delayed, we think that the experimental allowance program should be brought to full-scale operation within each experimental site as promptly as feasible. This probably entails a more rapid buildup of allowance-stimulated housing demand than would occur under a national program; but if there is to be any error in metering market impact, there is more policy value to testing the upper limit of the market's ability to "handle" excess demand than to experiment by understatement.
By rapid enrollment, we can provide the market with clear signals of the change in housing demand attributable to the experimental allowance program, thus prompting, we expect, faster reactions from housing suppliers with respect to both price changes and output changes, and a shorter time-path to the "long-run" market accommodation. The need for such clear signals of change in demand is all the greater in that the experimental program will have a greater barrier of skepticism to overcome than would a fully funded national program.

On these grounds, Rand originally proposed an enrollment plan that would enable the program to reach full scale within a year of its inception. Out of concern for adverse market effects, HUD preferred a slower pace, and we eventually agreed on a two-year schedule. That is, the HAOS were provided with the administrative capacity to enroll about 13 percent of all households in each site within two years, assuming that the number of eligible applicants conformed to our expectations.

We will try to substantially complete enrollment at each experimental site within two years. Thereafter, we expect a trickle of new applications from households who were at first unconvinced of the program's benefits or who were not at first eligible. Once enrolled, each participant must locate certifiable housing before his allowance payments commence; in our judgment, about half of all enrollees will find certifiable units within a few weeks after enrollment; the remainder will find it necessary either to wait for landlord-initiated improvements, or if they are homeowners, to undertake these improvements themselves. How long this process will take is unknown; it is one of the central research questions of the Supply Experiment. Certainly it would be optimistic to suppose that a plateau of allowance disbursement will be reached before 30 months from the opening of enrollment.

*We now believe that the two-year schedule was a wise choice from the administrative viewpoint, whatever its merits as a market stimulus. Despite considerable advance planning, the first six months of HAOS operations revealed many unanticipated procedural and staffing problems that would have seriously impeded any attempt to enroll households at a faster pace. Furthermore, the staff needed to handle the scheduled daily volume of applicants under a two-year enrollment schedule is about the same size as the staff that will be needed to operate the program once full enrollment is reached. Under a one-year enrollment schedule, a large force of temporary employees would have been required.*
ESTIMATES OF ENROLLMENT AND ALLOWANCE COSTS

Estimating enrollment and allowance costs for the Supply Experiment was not a single act but a continual process, for four reasons. First, until general program standards were firmly fixed, assumptions as to eligibility rules and allowance schedules were subject to change in ways that substantially affected the outcome for a given population. Second, until the experimental sites were firmly in hand, our estimates had to be based on illustrative rather than actual populations. Third, generally available data for illustrative populations were scanty; a considerable expenditure of staff time and money was needed to compile detailed population descriptions and adjust them to reflect current conditions. Fourth, our standard housing cost, \( \dfrac{v}{v} \), could not be finally determined until the screening survey had been conducted in each site and its findings had been analyzed.

These problems are now behind us, and it is possible to estimate the numbers of eligible households in each experimental site with reasonable reliability and currency. The remaining uncertainty relates to participation rates among those who are eligible. It has been the universal experience of income transfer programs that a sizeable fraction of those who are eligible for benefits do not participate. Some never learn about the program or inaccurately judge themselves to be ineligible. Others consider public assistance demeaning or think that program rules are onerous. Those who are eligible for only small benefits may feel that the benefits are simply not worth the trouble of applying for them.

By maintaining a posture of open enrollment and by interviewing nonparticipants as well as those who apply, we expect to learn how these considerations affect enrollment in the experimental housing allowance program by eligible households of various types. In the meantime, we can best look to experience in similar federal transfer programs as a guide.

Table 3.3 shows the participation rates on which we base our estimates of eventual program size and cost in each site. The base for each

\(^e\)Single persons with total incomes before assistance of $5,000 or more would not ordinarily be eligible for housing allowances under HASE program standards.

The rates are the number of eligible households rather than all households. The rates for single renters and for all homeowners are derived from national experience with old age assistance (now "supplemental security income") because single persons are ineligible for housing allowances unless they are at least 62 years of age and because most low-income households that own their homes are headed by elderly persons. The rates for renter households of two or more persons are based on national experience with aid to families with dependent children (AFDC), although allowance-eligible households of two or more persons do not always include dependent children.

In both cases, participation rates are assumed to decline as nonallowance income increases. Although the tables show participation rates for incomes of up to $10,000, a glance at Table 3.1 above will show the reader that HASE program standards exclude small households in the upper ranges of income; only families of three or more persons would usually qualify if total income from nonallowance sources exceeded $7,000.
By applying the program standards described earlier in this section to a population description obtained from a 10,000-household screening survey in each experimental site, we are able to estimate the numbers of households that were eligible to participate in the allowance program shortly before the opening of enrollment. The results are shown separately for renters and homeowners in Table 3.4 for Site I and in Tables 3.5 and 3.6 for Site II. (Table 3.5 gives countywide estimates, assuming that the program's jurisdiction will eventually include all of St. Joseph County; Table 3.6 gives estimates for the present program jurisdiction, the city of South Bend.)

Although we think these estimates are adequate for program planning, they must be qualified in several respects. First, our population description is based on sample interview data that are subject both to sampling variability and to nonresponse bias. Second, it was not possible to ask detailed questions about household income in a brief screening interview, so our information on current income for individual households is crude and no information was sought about assets whose values enter into the computation of income for program purposes.

Third, among those who completed the interview there were some who declined to answer even the simple income questions that were posed. Our data indicate that in September 1973 there were about 12,200 eligible households in Brown County, Wisconsin, Site I of the experiment (Table 3.4). Over half of these households were small, consisting of either one or two persons; and nearly two-thirds of them were homeowners.

Applying the participation rates shown in Table 3.3, we estimate that less than 60 percent of all eligible households are likely to enroll. About two-thirds of the enrollees will probably be small households and about half will probably be homeowners.

*For Site I, our income estimates are based on data reported by about 75 percent of all households scheduled for interviews. See David M. de Ferranti, Ira S. Lovy, and others, Screening Survey Audit Report for Site I, The Rand Corporation, WR-6884-HUD, November 1974, for an appraisal of the quality of the data. The audit of Site II screening survey records is not complete, but it is clear that nonresponse rates were higher there than in Site I.

**SOURCE:** Estimated by HASE staff from screening survey records for Site II (weighted final master file dated December 1974) and HUD-approved program standards for Site II.

**NOTE:** South Bend is currently the only jurisdiction in Site II in which the experimental housing allowance program is authorized to operate. Residents of housing units subsidized by other federal programs may be eligible to enroll in the experimental housing allowance program, but could receive payments only by moving to unsubsidized units.

<sup>G</sup> Excludes single persons under 62 years of age, who are ineligible unless displaced or handicapped. Also excludes lodgers in private homes, some of whom may be eligible but whose ages and incomes were not reported.
Comparing their incomes and household sizes with the schedule of values for $R^*$ given in Table 3.1, we conclude that the average annual allowance payment for renters will probably be about $862; for homeowners, our estimate is $675.*

If all 7,145 households shown in the table as participants had been enrolled and were receiving payments in September 1973, total payments would amount to $54 million annually, net of administrative costs. Of course, full enrollment is not expected until 1976, by which time the number of eligible households, their incomes, and the schedule of $R^*$ values could all be different. The annual contributions contract, based on earlier estimates, provides for a maximum of 6,096 allowance recipients at any one time, and for a maximum annual contribution of $9.2 million to cover allowance payments and program administration.**

Table 3.5 shows corresponding data for St. Joseph County, Site II of the experiment. There, we estimate that about 18,300 households were eligible in August 1974. About 60 percent of these households consisted of either one or two persons and about 60 percent were homeowners.

Applying the same detailed schedule of participation rates to Site II’s population as we did to the population of Site I, we estimate that about 67 percent of all eligibles will eventually enroll, a larger fraction than in Site I. This estimate, however, includes some 1,700 renter households already living in federally subsidized housing units who would be eligible for HAO assistance only if they moved to unsubsidized housing.*** Excluding them, countywide participation is unlikely to exceed 10,850 households, of which about 63 percent would be homeowners.

* Experience to date in Site I suggests that we overestimated average allowances for renters by about 10 percent. Among 924 renters receiving payments there in March 1975, the annualized average payment was $782 for renters; for 730 homeowners, the corresponding figure was $669.

** HASE research costs, including the field surveys described in Sec. IV, are funded separately.

*** There has been some discussion, as yet inconclusive, of the possibility of permitting such households to enroll in the housing allowance program and receive allowance benefits but to pay full market rent for the units they occupy. In 1974, there were about 1,400 subsidized units in Site II, including both public housing owned or leased by local
Because of our uncertainty about eventual interactions between the housing allowance program and other federal subsidy programs in Site II, the estimated numbers of participants shown in Table 3.5 must be regarded as an upper bound. But using these numbers, we estimate that the average allowance payments in 1974 under Site II's schedule of \( R^* \) values would be about the same as those for Site I in 1973.

If all 12,194 households shown in the table as participants had been enrolled and were receiving payments in 1974, total payments would amount to $9.2 million, net of administrative costs. However, full enrollment is not expected until 1977, by which time several factors affecting this estimate may have changed. In any event, the annual contributions contract for Site II provides for a maximum enrollment of 9,638 households at any one time; the maximum annual contribution of $17.5 million is clearly more than adequate to cover allowance payments and administrative costs for that number of participants.

Table 3.6 shows corresponding data for the present program jurisdiction in Site II—the city of South Bend—and excludes from consideration all those now living in federally subsidized housing. It thus provides an approximate lower bound to the size and cost of the Site II allowance program; but it still must be remembered that participation in the program may fall short of our estimate.

We estimate that in 1974 there were nearly 9,400 eligible households in South Bend. Their division into small and large households and their division by tenure is about the same as for the county as a whole.

Applying the same detailed participation rates as before to a base consisting of eligible South Bend residents living in unsubsidized housing, we estimate that about two-thirds of them will eventually enroll in the program. Of those enrolling, we expect about two-thirds to be small households (one or two persons) and about 60 percent to be homeowners. Average allowance entitlement for these households is about the same as for participants in a countywide program.

Housing authorities and apartments subsidized under Sec. 221(d)(3) and Sec. 236 of the National Housing Act, as amended. The number of subsidized units in Site I was smaller—about 1,300 units, of which 700 were owner-occupied homes assisted under Sec. 235 of the same law.
If all 6,295 households listed in Table 3.6 as participants had been enrolled and were receiving payments in 1974, total payments would amount to $4.8 million, net of administrative costs.

Thus, we can imagine a range of program sizes in Site II, depending on final program jurisdiction and the extent to which those now living in federally subsidized units are able to participate. Maximum enrollment could be as small as 6,000 households or as large as the ACC ceiling of 9,638 households. Allowance payments could range from $4.8 million to about $7 million (for 9,638 households) if average allowance entitlement for 1974 did not change over the life of the program.
IV. MONITORING THE EXPERIMENT

The experimental allowance program, described in the preceding section, is designed to stimulate low-income demand for housing services in ways that are comparable to the effects of a permanent national program of housing allowances. Having thus provided the experimental stimulus, our second task is to monitor the response. This section explains how we propose to gather the data that will, when properly analyzed, lead us to conclusions about the effects of the allowance program on the supply and price of housing services in the local market and on the behavior and attitudes of the various participants in that market: landlords, homeowners, real-estate investors, market intermediaries, factor suppliers, and consumers of housing services, both program participants and others.

Some of the information we seek will be routinely generated by the RA0 as a by-product of its administrative processes. Some will be gathered through a set of sequenced and related field surveys designed especially for our purposes and administered under our supervision. Local public records and general sources such as the U.S. Census of Population and Housing will also be tapped. Finally, we will maintain at each site a resident observer whose principal function is to fill in the gaps of our knowledge through special-purpose inquiries and to assist our interpretation of systematic data through wide-ranging informal observation.

Below, we describe our plans for each kind of data-gathering activity, emphasizing method and content. In Sec. V, we explain how the data thus acquired will be organized into research files and, in general terms, how they relate to each of the major research questions addressed by the Supply Experiment. Subsequently, in Secs. VI through IX, we address each major research question in turn, indicating the data and explaining the methods of analysis that we expect to use in seeking answers.
MONITORING THE ALLOWANCE PROGRAM

Although a significant number of program participants will be interviewed in our field surveys, our main source of data about the allowance program will be the HAO's administrative records. These records provide a complete enumeration of enrollees and complete coverage of transactions with each enrollee during his participation in the program.

With few exceptions, these records contain only information specifically needed to operate the program efficiently and to guard against fraud. This fact reflects an early policy decision not to use the HAO as a vehicle for gathering research data that could be obtained by other means. Even so, the records should be extremely useful in our research, especially those relating to enrollment, disbursement of allowance payments, and evaluation of participants' housing.

Enrollment and Disbursement Records

As we explained in Sec. III, each applicant for housing assistance will be required to supply detailed information about the size and composition of the household on whose behalf assistance is sought; about the amount and sources of income received by its members during the preceding year and also their current assets; about the household's place and type of residence at the time of enrollment; and about its current housing expenses. All this information must be documented to the satisfaction of the HAO, inasmuch as it is the basis for determining eligibility and the amount of allowance entitlement.

Although enrollment records do not contain any information on educational attainment or occupation, they do report the applicant's race and provide an unusually thorough account of family composition and current economic status. They also exactly identify the applicant's place of residence, the basic characteristics of his housing, his tenure, and his explicit housing expenditures. For renters, the last item includes contract rent and the allocation of responsibility for utility bills as between tenant and landlord. Homeowners report the assessed value of their homes, financial details of encumbrances such as mortgages, and the amounts of monthly mortgage interest payments, real-estate taxes, and insurance.
The procedure adopted by the HAO entails semiannual recertification of eligibility and recomputation of allowance entitlement for each participating household. Thus, the participant must report changes in household size, income, or housing costs at six-month intervals and his basic enrollment record is updated accordingly. In the interim, the HAO maintains a current address register and record of monthly allowance payments. Thus, for the duration of its enrollment, each household participating in the program will be represented by a semi-annually updated file, with a cumulative history for each data item.

This rich research material will be regularly transmitted by the HAO to Rand, where it will be organized into research files, as described below in Sec. V. These files will enable us to track all recipients as they move within the experimental site and to correlate these moves and associated changes in housing circumstances with changes in the recipients' personal circumstances, whether due to allowance benefits or to other causes.

**Housing-Evaluation Records**

Administrative requirements of the allowance program will result in a second rich source of experimental data in the form of housing-evaluation records. Once enrolled, a household will not be entitled to allowance payments until it occupies a housing unit that has been evaluated by the HAO and certified as to size and quality. If the participant remains in residence, the unit will be reinspected annually; if he moves, his allowance will be discontinued unless his new home is also evaluated and certified.

Thus, for every participant, the HAO will compile a series of housing-evaluation reports, perhaps irregular in interval (but with a maximum interval of one year), and shifting in their reference as the participant moves.

The reporting form includes a precoded description of the residential building and its site; a room-by-room evaluation of the housing unit (space, lighting, ventilation, facilities, and privacy); and ratings of some 22 elements of the exterior and interior of the building and housing unit with respect to safety and sanitation. Deficiencies that
must be corrected to bring the unit to certifiable condition will be systematically identified so that reevaluations, if requested, can readily check whether appropriate improvements have been made.

The HAO will regularly transmit these evaluation reports to Rand, where they will be organized into research files that are linked to enrollment and disbursement records. Thus, for each allowance recipient, we will have regular and thorough reports on the quality and condition of his housing, as judged by professional evaluators.

Other Records

While enrollment and disbursement records and housing-evaluation reports are the principal sources of research data to be obtained from the HAO, a variety of other records may also prove useful. In particular, data from the counseling program for enrollees, records of grievance procedures, and logs of inquiries and complaints maintained by the HAO may alert us to features of the program or to circumstances in the housing market that call for further investigation. Additional housing information for renters may be garnered from the lease agreements that recipients must submit to the HAO for approval. Whether or not these records are systematically abstracted from the beginning for analytical purposes, the HAO record system will be designed to prevent their loss; they will therefore be available for retrospective study.

MONITORING THE HOUSING MARKET

As explained above, records of the allowance program will provide information about the characteristics of all allowance recipients, their movements within the experimental site, their ability to find certifiable housing, the characteristics of the units they occupy, and their housing expenditures. However, the issues addressed by the Supply Experiment cannot be resolved solely by attention to allowance recipients and their housing. We must cast a wider net in order to understand how the allowance program affects the local housing market and its various participants, only a small fraction of whom are allowance recipients.
As our principal basis for market-wide observation, we will select a panel of residential properties—both owner-occupied homes and rental properties—and monitor each property, its owner, and its tenants for the duration of the experiment, systematically recording data of interest by means of an annual cycle of field surveys. As compared with independently selected annual samples, a longitudinal panel has the immense advantage of enabling us to measure changes over time for individual elements of the sample and to relate the specific circumstances of a sample property at one point in time to subsequent events involving the same property. By jointly rather than separately selecting the properties, the owners, and the tenants to be surveyed, we greatly enrich the data obtained for each of the three elements by cross-reference to data obtained for its associated elements; to put the case differently, our monitoring plan gives us multiple perspectives on the system of interactions between the housing provided by a particular property, its tenants, and its owner, each element affecting and affected by the others.

The thread of continuity in this monitoring plan is provided by keying observations to tax parcels—sample elements that can be precisely defined, are stable over time and easily located from one year to the next, and into which the entire experimental universe can be divided. Our panel will be initially selected from all such parcels within the boundaries of the experimental site that are in residential use at the beginning of the monitoring program. To keep it representative of the current housing stock, it will be updated annually by sampling building permits and adding new residential properties to the panel.

Sample Design for a Panel of Residential Properties

In choosing the residential properties to be thus monitored, we are guided by four general considerations, whose sampling implications are broadly indicated below:

Field experience suggests qualifications for all these propositions.
1. From our sample observations, we want to be able to generalize about events in the local housing market as a whole. Therefore, we must include residential properties representative of all sectors of the market, each sample element having a known probability of selection.

2. For different sectors of the local housing market, we anticipate different degrees of stimulation from the allowance program and also different patterns of response. We want to be sure that each sector of interest is well enough represented so that we can generalize about its particular response to the allowance program.

3. Since we are particularly interested in the effects of the allowance program, we want our generalizations to be especially reliable for those sectors in which the program has major effects. To the extent that we can identify those sectors ahead of time, we should concentrate our monitoring resources on them.

4. Although generalization about the effects of a housing allowance program on housing markets other than our two experimental sites will necessarily entail large elements of judgment, transferability of our findings will be enhanced by their sectoral disaggregation. We want to define our market sectors so that corresponding sectors can be identified elsewhere from generally available data, and to pay particular attention to sectors that may be unimportant at our experimental sites but are prominent elsewhere.

Our resolution of these issues is embodied in a "modified impact-gradient" sampling plan that entails random sampling of properties within each of 18 strata. The strata are defined to distinguish (a) probable differences in the degree to which housing demand will change due to the allowance program, and (b) probable differences in the supply response to a given demand change (e.g., in the price elasticity of the supply of housing services). As shown in Fig. 4.1, 16 of the strata are defined along four dimensions: tenure, housing-market
Fig. 4.1 - Stratification of residential properties for modified impact analysis.
density, number of units, and rent or value. Two additional strata of specialized housing are formed (mobile homes and rooming houses) without subdivision along those dimensions.

Our analysis plan entails longitudinal analysis of data for individual properties; consequently, our sample design is keyed to target numbers of properties with five-year complete survey records. We chose the price elasticity of the supply of housing services as the parameter whose estimated sampling distribution guides the setting of stratum-specific reliability targets and sample sizes; estimates of other parameters will differ in reliability from estimates of supply elasticity, but the same general pattern of stratum differences in reliability will apply to them also.

Overall, we seek about 900 complete five-year property records in each site, a figure derived by balancing costs against reliability of

---

*Housing-market density is intended to distinguish properties in urban and rural neighborhoods. Operational considerations led us to approximate this distinction simply by dividing the metropolitan area into an urbanized core and a surrounding rural area, each sector possibly containing some neighborhoods whose local density is inappropriate for the distinction sought.

** Details of sample design have been one of the least stable aspects of the experiment, changing to accommodate new information about the populations to be sampled, new resource constraints, and experience with field procedures.

The logic of Rand's initial proposal is developed in Timothy M. Corcoran, Eugene C. Foggie, and Tiina Repnau, Sample Design for the Housing Assistance Survey Experiment, The Rand Corporation, R-8029-HUD, November 1972. There, we proposed 32 sampling strata and a range of possible sample sizes. Subsequent agreement with HUD on a sample size near the low end of this range led us to collapse the sample into 16 strata. Field experience in Site I led to the creation of five additional strata, three for special types of residential properties and two for nonresidential properties likely to become residential in the near future. These changes are reflected in Timothy M. Corcoran, Survey Sample Design for Site I, The Rand Corporation, WN-8040-HUD, March 1974.

In June 1974, after baseline surveys in Site I were completed, budget problems led to a further reduction in sample size and deletion of three of the special strata. See Elmer Lewis, Survey of the Housing Assistance Survey Experiment, The Rand Corporation, R-1859-HUD, October 1974, pp. 59-64, for details.

Here, we present the sample design actually used in selecting the permanent panel for Site I.
parameter estimates. To achieve this completion target, the panel of properties to be surveyed each year must be considerably larger, allowing for failures of landlords, tenants, and homeowners to respond adequately (or at all) to interviews over the planned five annual survey cycles.\* We currently plan a panel of about 2,050 properties in each site. Figure 4.2 shows how we think the panel for Site I should be allocated within each dimension of stratification, that being the level of detail most helpful for the present discussion. Because the sample design reflects characteristics of each site's population, target sample sizes for Site II will differ slightly from those shown for Site I.

We propose to select 2.5 times as many rental properties as owner-occupied homes, to reflect the greater diversity of rental housing and its greater accessibility to allowance recipients. Among rental properties, the number of large multiple dwellings in the panel is limited by their scarcity at our experimental sites; because this kind of housing is more prevalent in other markets, we will aim at (but doubtless fall short of) complete enumeration. Although we seek equally reliable information for small multiple dwellings and single-family rental houses, we also expect to lose substantially more of the latter due to non-responses in annual survey cycles; thus, we shall begin with a larger number of single-family houses.

We propose to draw about 80 percent of the panel from among residential properties located in the urbanized area, reflecting our interest in the greater complexities of housing-market interactions in an urban setting.

For rental housing, we propose to draw about 82 percent of the baseline panel from the two lowest terciles of baseline rents, this being the portion of the market within which we expect allowance recipients to be active. For owner-occupied housing, we propose to draw

\* The survey instruments applicable to each type of property are described below. Since estimates of nonresponse differ for landlords, tenant, and homeowner interviews, our discussion of this topic and estimates of the numbers of properties of each type for which five-year complete records will be obtained follows the discussion of the instruments themselves.

**See Sec. X, "Inference from Experimental Findings."
Fig. 4.2—Proposed composition of panel of residential properties, by major dimensions of stratification.
about 80 percent from the two lowest quartiles of the value distribution, for the same reason. *

A panel of 2,074 residential properties, divided among single-family houses and multiple dwellings as shown in Fig. 4.2, would contain about 5,300 housing units. However, we do not propose to try to interview all tenants in larger multiple dwellings, ** so the total number of housing units for which individual data will be sought should approximate 3,350. In our two experimental sites, the numbers of housing units are about 50,000 and 80,000 respectively, so that those surveyed will comprise about 7 and 4 percent of the respective totals.

**Sample Selection**

Selection of the baseline panel of residential properties entails a complex sequence of steps that differ in detail in the two experimental sites because of differences in the kinds of data available to assist the process. In general, we planned a multistage sampling procedure that would limit the effort expended on acquiring data for properties that do not end up in the final panel, yet would not violate the rigorous canons of probability sampling. ***

The sampling frame is essentially a list of all tax parcels within the boundaries of the experimental site. With the aid of tax records and local directories, these are stratified by location (urban or rural) and by residential or nonresidential use. The residential properties are further stratified by tenure, number of units, and assessed value per unit (which serves as a temporary proxy for both value and rent). These strata are then sampled at roughly twice the rates required to

---

*Prosperous households have a greater affinity for homeownership than for renting, and this is reflected in the values of their homes. Thus, a smaller fraction of the total distribution of owner-occupied homes than of rental units is likely to be accessible to allowance recipients, and our sample allocation should reflect this fact.*

**See "Survey of Tenants and Homeowners," below.

obtain the desired number of elements in the baseline panel. Each parcel thus selected is entered on a screening list.

The second stage of sample selection entails field listing and a screening survey. Each property on the screening list is visited by fieldworkers, who confirm or amend the stratification data obtained from tax records and directories and conduct brief interviews with the residents of some or all housing units on the property. This survey not only aids in sample selection, it also prepares the way for the baseline surveys to come by providing information on the ownership of the property and on the tenure of resident households—information that aids in selecting appropriate baseline instruments for each property. Finally, it provides early data on housing characteristics and rent for a large number of rental units and on household size and income; these data are used by the HAO to determine appropriate standards for housing assistance and to estimate the numbers of eligible households in the site.* The contents of the screening instrument for Site I are summarized in Table 4.1; the instrument for Site II is similar.

The screening list, as amended by the reports from the screening survey, is then again sampled to obtain a smaller list of properties in each stratum, the baseline names list. Each property on this list is scheduled for administration of the appropriate baseline survey instruments, described below. When the lengthy and expensive process of baseline interviewing is complete, the records are reviewed for critical elements of nonresponse, as well as for misclassifications that survived earlier screens. The last step is to select from the baseline survey list the final panel of residential properties, for each of which an adequate baseline record has been obtained, and each of which will then be monitored by annual resurveys over a period of five years.

Baseline Surveys

For each member of our baseline sample of residential properties, we have undertaken a set of field surveys to gather systematic data on

*See Sec. III, above.

NOTE: This summary is based on the final version of the screening survey instrument, as approved by OMB and HUD on 7 August 1973 (OMB No. 63-S-73027; HUD No. R-3-1A).

conditions immediately prior to the commencement of the allowance program: descriptions of the property and the neighborhood in which it is located; characteristics and attitudes of the households that live on the property; characteristics, management policies, and plans of its owner; and a full account of property revenues and expenses. These data will serve as a baseline or point of reference against which subsequent events involving each property can be assessed.

Altogether, we are administering four major survey instruments in this pre-enrollment cycle of fieldwork, though not all of them will be
administered to each property in the sample and some of the instruments have more than one format. The instruments used in Site I are described below; those for Site II are similar.

**Neighborhood Survey.** The territory of each experimental site has been divided into mutually exclusive neighborhoods, and data on the characteristics of each such neighborhood will be compiled from public records and by field observation. Within the urbanized portion of each site, neighborhoods are small in area and laid out so as to contain relatively homogeneous populations and housing stocks; rural neighborhoods are larger in area and less homogeneous. We have attempted to make their boundaries conform to areas defined for statistical purposes by the 1970 Census of Population and Housing and by local planning agencies. Neighborhood populations vary in size, usually ranging between 1,000 and 4,000 households. The information sought relates to such topics as land use, general type and condition of residential buildings, availability of various public facilities and municipal services, and the general amenities of the neighborhood (see Table 4.2).

**Survey of Residential Buildings.** Each property selected for inclusion in our baseline sample will be visited by a fieldworker, who will supplement and amend previously obtained tax record data by direct observation of the physical features and condition of the residential buildings on the property. This inspection is restricted to exterior aspects of the residential buildings and, for multiple dwellings, to public areas of the interior. No attempt will be made to inspect the interiors of individual housing units, on which some data will have already been gathered by the screening survey and on which more will be gathered by the survey of tenants and homeowners, described below. The items covered by the survey of residential buildings are summarized in Table 4.3.

**Survey of Landlords.** For each rental property in our baseline sample, we will seek out the owner or his representative for an extensive interview, which includes five general lines of inquiry. First, we seek data on the characteristics and circumstances of the owner and his activities in the real-estate market. Second, we seek a

</tbody>
</table>

**NOTE:** This summary is based on the final version of the residential building survey instrument as approved by OMB and HUD on 20 August 1973 (HUD No. H-1-13).

a Grid items are counted as separate questions.

b Applicable only to multiple dwellings.
detailed account of his mortgage financing and his income and expenses from the property during the preceding year. Third, we try to elicit his perceptions of the neighborhood housing market and of the prospects of his property there as an investment. Fourth, we seek information on his management policies and on his relationship with his tenants and with suppliers of supporting services. Fifth, we ask about his plans for the property and how they may be affected by the housing allowance program.

For convenience in administration, the survey instrument is divided into modules generally differentiated by subject matter, although other considerations prevent strict application of this principle. Table 4.4 summarizes the contents of each module of the Site I instrument.

Survey of Tenants and Homeowners. Households living on each property, already briefly interviewed for screening purposes, will be revisited for more extensive baseline interviews. We attempt to interview every household occupying a single-family house or small multiple dwelling; in multiple dwellings of five units or more, we randomly select a sample of units whose tenants are to be interviewed. *

The purposes and contents of this interview differ for rental tenants and for homeowners. In either case, we seek a careful account of household membership and relationships, amount and sources of income, and the nature and location of employment for household heads. We also try to determine the respondent's self-identification with various social groups and the degree of household involvement in the activities of formal organizations, in extended-family relationships, and in neighborhood social life.

Having thus "placed" the household in the social and economic systems of the community, we pursue three main lines of questioning. One is a detailed history of residential mobility and associated changes in family composition, employment, income, and housing circumstances. The second, differing for owners and tenants, is a thorough exploration

* In Site I, up to eight units per property were selected, of which four were included in the permanent panel. In Site II, more complex rules were developed to deal with a few extremely large (up to 800 housing units) properties.

**Note:** This summary is based on the final version of the landlord survey instrument, as approved by OMB and HUD on 12 October 1973 (OMB No. 63-S-73043; HUD No. H-3-5A).

*Grid items are counted as separate questions; repetitions for multiple occurrences (e.g., more than one mortgage) are not.*
of current housing and neighborhood characteristics and the respondent's view of his situation: his attitudes toward his housing, his landlord, and his neighborhood. Finally, we try to obtain detailed information on housing expenses during the preceding year: contract rent for renters; mortgage financing, taxes, and insurance for homeowners; and for both, other outlays such as utility payments and expenses (or own efforts) for maintenance, repairs, and improvements.

Although relatively few baseline respondents are likely to be familiar with the housing allowance program (then still in the planning stage), a few questions are included to test their knowledge of the program and their attitudes toward it.

This survey instrument is also divided into modules for ease of administration. Table 4.5 summarizes the contents of the general instrument used in Site I. Special versions were developed for residents of mobile homes and lodgers in rented rooms. If a unit is vacant, the interviewer completes a brief vacancy report that includes such information as can be obtained by observation or from neighbors.

**Complete Property Records**

Taken together, these four surveys comprise the baseline for our sample of residential properties. The survey of neighborhoods is not property specific; Table 4.6 shows which of the other three survey instruments—for residential buildings, landlords, and residents of the property—are used in which situations, both at baseline and in the annual cycle of postenrollment surveys discussed below.

To be eligible for inclusion in the permanent panel and thus scheduled for postenrollment surveys, a property must have a baseline survey record that is substantially complete. For a homeowner property, a complete record consists of a completed residential building report and a completed interview with the owner. For a rental property, we require a residential building report, a landlord interview, and either a vacancy report or an interview with at least one tenant. Analogous rules apply to mobile home and rooming-house properties.

Note: Ownership properties are those whose housing units are all owner occupied or are being held for owner occupancy; with rare exceptions, they are single-family houses. A property with one or more housing units occupied by a renter or available for rent is a rental property even though there may be a resident landlord. A mobile home property is one on which at least 25 percent of the housing units are mobile homes, regardless of tenure. A rooming house is a property with space for five or more lodgers each of whose quarters fail to qualify separately as a housing unit.

1. Administered to the owner of the property, whether or not he resides on the property.
2. Administered to the owner if the property is not available for rent.
3. Homeowner instruments are not administered to resident landlords.
4. Some rooming houses and mobile home properties also contain regular rental housing units.
5. Administered if applicable. Lodgers share housing units with homeowners or tenants on some properties not classified as rooming houses.
6. Administered if applicable. Mobile homes exist as extra rental units on some properties not classified as mobile home properties.
Our ability to fill the strata of our permanent panel with the target numbers of properties depends of course on whether baseline surveys are completed on enough properties of each type. In Site I, where the permanent panel has been selected, we fell short in some strata within which close to complete enumeration was planned, usually because we overestimated the number of properties existing in the population; and we found (and added to the panel) more large rental properties than we expected. Losses due to survey nonresponse were generally about as anticipated.*

Postenrollment Surveys

The baseline surveys just described require several months to complete and are followed immediately by a general invitation to the public to apply for enrollment in the experimental housing allowance program. We do not expect all those who are eligible to apply immediately, and additional households will become eligible in subsequent years as their circumstances change. Office procedures and staffing for the HAO are geared to a two-year schedule of heavy enrollment which, if enough applications are received during that time, will bring the program to the maximum size permitted by the program's Annual Contributions Contract with HUD. Thus, by the anniversary of the baseline surveys, the experimental allowance program will be well under way.

On that anniversary, and each year thereafter for a total of five years, ** we propose to resurvey each property in our baseline panel, using modified versions of the four survey instruments described above. These instruments will cover much the same ground as their baseline counterparts, but with emphasis on detecting changes that have occurred

---

*See *First Annual Report*, Tables 4, 5, and 6.

** Baseline surveys on each site ran from November to April. Second-wave and subsequent surveys are scheduled for January to April. Most time-oriented data are keyed to the calendar year preceding the survey.

The duration of the monitoring program is not firmly fixed; it will depend in part on the observed course of events at each site. Five years is our estimate for planning purposes.
since the prior survey. In addition, no doubt, experience with each instrument will provide us with reasons to modify the wording or the tactics of some lines of questioning, and we will discover information needs not now foreseen.

**Survey of Neighborhoods.** We will repeat this survey at 30-month intervals (rather than annually) for each neighborhood defined at baseline, looking for changes in land use and traffic patterns; for evidence of residential construction, improvements to existing properties, conversions, demolitions, or abandonment; for changes in the availability or adequacy of public facilities and municipal services; and for changes in general amenities.*

**Survey of Residential Buildings.** We will repeat this survey annually, then compare the records with those for previous years, searching for evidence of changes in use or occupancy and in the physical characteristics and condition of each building. This information will help the analyst to verify financial data on repairs or improvements reported by the property owner and will also provide direct evidence of housing improvement or deterioration over time. This survey will also cover an annual sample of newly constructed housing throughout the site, drawn from building permit data; these properties will be added to our panel and thereafter subjected to all appropriate surveys, depending on the nature of the residential use (e.g., rental vs. ownership).

**Survey of Landlords.** Here, our primary interest lies in obtaining from the owner an accounting of income and expenses for the preceding year, an accounting that can be compared, item by item, with the corresponding records from previous survey cycles. If there has been a change in ownership during the preceding year, we will not only try to obtain "baseline" data on the new owner, we will also seek out the prior owner in order to complete the record of income and expenses.

*Originally, we planned to repeat this survey annually. However, partly for budgetary reasons and partly because we do not expect rapid changes in the items to be observed, we concluded that a 30-month interval between surveys would be adequate.
We also want especially to capture evidence of changes in occupancy, rent levels, and kinds of tenants; and to note changes in the owner's perception of the neighborhood housing market and the specific prospects for his property—changes that may affect his investment strategy or maintenance policy. In this connection, we are particularly interested in his perception of the effects of the housing allowance program and in his attitudes toward it.

Survey of Tenants and Homeowners. We anticipate frequent changes of tenancy, particularly in rental housing. When we encounter new residents, the scope of the survey will be about the same as at baseline, including the mobility history. Households that have been interviewed in previous cycles will be reinterviewed to check for changes in household composition, income, and employment. In either case, we will seek evidence of changes in the interior physical characteristics, facilities, and condition of the housing unit and a record of housing expenses for the preceding year. Finally, we will again probe for each respondent's attitudes toward his housing, his landlord, and his neighborhood.

After baseline, both tenants and homeowners will have had an opportunity to apply for enrollment in the housing allowance program. Our annual reinterviews will inquire of each respondent whether he has applied and how he feels about the program's effects on his household, his neighborhood, and the community as a whole. Those who have applied will be asked a more detailed series of questions about their current status in the program and their views of program benefits, obligations, and administrative procedures.

Occasionally, single-family homes in our panel will be vacant at the time of our annual resurvey, so that no tenant or homeowner interview is possible. In these cases, we will seek out the owner and administer relevant modules of the homeowner landlord instrument, as appropriate. We may also find that a formerly residential property has been withdrawn from the housing market or converted to other uses, and we will try to find out why.
The Effects of Survey Nonresponse on Record Completion

Most panel surveys face a problem of respondent attrition as individuals die, leave the area in which the survey is conducted, or cease to cooperate with interviewers. To counter this problem, initial panel sizes are usually made larger than would otherwise be appropriate, or else dropouts are replaced by new respondents whose characteristics are similar.

In our survey design, the sample elements are residential properties and specific housing units on each property. The properties themselves are imperishable and immobile, although housing units may be demolished or merged and whole properties may be converted to nonresidential use. Such events are not viewed by us as inconveniences, but as phenomena that we want to observe. Thus, properties will not be dropped from our panel under any foreseeable circumstances, although different survey instruments may be administered following a change in the use of a property.

For us, the problem of panel attrition is confined to information losses due to our inability to complete the set of survey instruments applicable to a given property in a given survey cycle. Usually, more than one instrument is applicable, and even with the best scheduling and interviewing techniques, some of the subjects will not be located, will refuse to talk to the interviewer, or will decline to answer some questions. Thus, for any particular property, the proportion of information sought but not obtained in a given survey cycle may be anywhere from trivial to total.

Fieldwork quality-control procedures include establishing standards for "substantial" completion of each survey instrument, with provision for appropriate follow-up when the initial interview fails to result in a completed questionnaire. Failure to complete all the appropriate instruments will impinge most directly on the selection of the baseline panel, for each member of which all essential data must be obtained. Thereafter, while exerting best efforts to obtain high response rates, we will have no choice but to suffer the statistical consequences of nonresponse.
Working from estimates of nonresponse rates to individual surveys, we calculated the cumulative effects in terms of information loss over a five-year period.* The effects differ with the kind of residential property, depending on the applicable survey instruments; and the applicability of the various instruments changes when the status of the property changes—e.g., from occupied to vacant or from owner-occupied to rental. Finally, expected response rates in a given year are contingent on the nature of the response in the prior year.

Although other assumptions are also required, the key estimates of response rates are those for the landlord and the tenant and homeowner interviews, shown in Tables 4.7 and 4.8 by size of structure and experience in the prior year. For multiple dwellings, we require only one completed tenant interview (although more will be sought).

<sup>a</sup>In applying these rates, we assume that 20 percent of all households move each year.

<sup>b</sup>Approximate probability of completing at least one tenant instrument when interviews are attempted for all tenants in structures of 2 to 4 units and six interviews are attempted in structures of 5+ units. For two-family structures, a more exact estimate is .98; for three-family structures, .997.

<sup>c</sup>Probability of completing no tenant instruments is negligible.

Calculations from these assumptions (using Markov chains of conditional probabilities) led us to the results shown in Table 4.9. At the end of five annual survey cycles, we anticipated having complete survey records for about one-third of the single-family rental properties in the baseline panel, one-half of the small multiple dwellings, and two-thirds of the large multiple dwellings. For single-family owner-occupied structures, we expected complete data for about 44 percent of those in the baseline panel.

To be sure, incomplete records will not be total losses from an analytical point of view: Nonresponse in Year 2 may be partly remedied by full response in Year 3, and nonresponse by a tenant is less serious

SOURCE: Calculations by HASE staff.

NOTE: A complete record for a rental property is one for which a residential building instrument, a landlord instrument, and at least one tenant instrument (or a vacancy report) are completed at baseline and annually thereafter; for an ownership property, a complete record is one for which a homeowner instrument is completed at baseline and annually thereafter.

Percentage distributions by completeness of terminal record are based on the number of properties for which baseline instruments were completed.

than nonresponse by both tenant and landlord. As Table 4.9 shows, our nonresponse assumptions imply that an additional 12 to 21 percent of each class of structure will lack complete records for one year only.

Although our prior estimates of baseline response rates were not far off the mark in Site I, we cannot yet tell whether response rates in subsequent resurveys will conform to the estimates given in Tables 4.7 and 4.8.* There is little relevant experience, especially in

*We do know now that our assumption that 20 percent of all households move each year, noted in Table 4.8, is inappropriate. Although 20 percent is a correct overall figure, we have found in Site I that about half of all renters move each year vs. less than 10 percent of all homeowners. Our record-completion model is based on census data that did not differentiate mobility rates by tenure.
surveying landlords, to guide us. It is therefore quite possible that we will end the monitoring program with substantially fewer than our target of 900 five-year complete property records for each site. The opposite outcome is not likely, because we have assumed very high response rates in subsequent cycles for those who complete their first interview.

Characteristics of the Terminal Panel

The baseline panel and its allocation among housing-market strata, illustrated earlier in Fig. 4.2, was inflated in size to allow for the information losses due to nonresponse that are reflected in Table 4.9. The size and composition of the corresponding terminal panel, consisting of all members of the baseline panel for which we expect to obtain complete five-year survey records, is illustrated in Fig. 4.3.

Given a baseline panel of 2,074 residential properties allocated as shown earlier, we would expect to end the monitoring period with complete survey records on about 929 properties, about 45 percent of the original total.* The rate of loss by stratum varies, for the reasons we have indicated. As reflected in this condensed display, the most notable change in interstratum proportions is between single-family rental units and small multiple dwellings. Beginning with 39 percent more of the former than of the latter, we end with 9 percent fewer.

As nearly as we can now determine, the statistical properties of this terminal panel will enable us to carry out those aspects of our analysis plans that rely on panel data with reasonable confidence in the results. The issues entailed in this assessment are too complex for easy summary; here, we wish only to leave the reader with a general understanding of our panel's size and composition, of the monitoring program addressed to it, and of the end product.**

---

* This figure does not include the planned annual additions to the panel of about 40 new residential properties, sampled from building permits.

** See Corcoran, Poggio, and Repnau, Sample Design for the Housing Assistance Supply Experiment, for an assessment of the statistical properties of the sample of residential properties; and Adele Massell
Fig. 4.3—Expected numbers of five-year complete property records, by major dimensions of stratification
Testing for Nonresponse Bias

The procedure described above for selecting the panel of residential properties to be monitored over time is carefully designed so that the properties selected for baseline surveys will be a random sample of all properties in their respective strata. However, if a property is to be included in the panel, we must obtain baseline data from both the owner and, for occupied rental properties, at least one tenant. If those who are willing to be interviewed differ in other important respects from those who are unwilling, the panel will not be representative of the population from which it is drawn.

Nonresponse bias is always a danger in field surveys; moreover, since the relevant characteristics of nonrespondents can seldom be ascertained, the extent of the bias and its effect on subsequent analysis of the data are difficult to determine. In the present case, however, we see several ways of evaluating nonresponse bias as it affects the sampling validity of our panel of residential properties, their owners, and their occupants.

Our main concern is to obtain adequate information about the properties excluded from the panel because of baseline nonresponse. Usually, the problem will be that the landlord of a rental property or the owner-occupant of a homeowner property could not be contacted or refused to be interviewed. In either case, we have three possible sources of information about the property. One is the tax record, which identifies the owner, describes the property and its improvements, and estimates its market value. The second is the residential building report for the property, described above in Table 4.3, which can be completed by a fieldworker without the owner’s cooperation. It

* Following a review of baseline nonresponse problems in Site II and plans for analyzing nonresponse bias, it was decided to seek residential building reports only on properties whose owner had been successfully interviewed.
 describes the physical characteristics of the property and its neighborhood in some detail. Finally, for refusals (though not for contact failures), refusal forms completed by our interviewers report their impressions of the owner's personal characteristics (age, sex, race, income).

For homeowners and tenants who do not respond to baseline interviews, we are likely though not certain to have still another valuable source of information in the form of screening interviews that they completed several months earlier. These records, described above in Table 4.1, include considerable detail about household characteristics and characteristics of the housing unit. Because properties were considered eligible for the baseline surveys even if their occupants did not complete screening interviews, screening records may not be available for all baseline nonrespondents; indeed, a screener refusal seems fairly likely to be followed by a baseline refusal.* Moreover, some households that were screened will have moved, so that the baseline nonrespondent is a different household from the one for which a screening record is available. On the other hand, it should be noted that resident landlords were usually screened, so we have information about their personal characteristics as well as about their properties even without a baseline landlord interview.

We are confident that we can compile from these sources a basic profile of the properties excluded from the permanent panel because of baseline nonresponse, including characteristics of their owners and their tenants, that will enable us to compare them with the properties included in the panel and thereby to detect any serious sampling biases.

Once a property has been empanelled, there may be further problems of nonresponse in subsequent survey cycles, but detecting nonresponse bias becomes much easier. With a complete baseline record on the property, its owner, and its occupant, it is easy to compare respondents to nonrespondents for any given survey. This proposition must

*In Site I, screening interviews were completed in 86 percent of all cases in which they were attempted. In Site II, the completion rate was lower, about 65 percent.
be qualified by noting that a postbaseline nonrespondent may be a new owner or occupant for whom no previous interview records are available. However, both the property and the housing unit will have been thoroughly described; also, we obtain some information about tenants from the landlord and vice versa.

If nonresponse bias is detected either in the composition of the permanent panel or in the file of complete records for subsequent survey cycles, the next issue is to evaluate its seriousness. This can only be done in the context of a specific analytical issue, but generally the incidence of nonresponse is likely to be low enough so that even a substantial difference between respondents and nonrespondents has little effect on estimates of population parameters. Although it is possible and sometimes desirable to reweight the sample of respondents to compensate for a known nonresponse bias, usually doubts about conclusions can be resolved more simply by "worst case" analysis.*

The Household Sample

The monitoring program described above includes annual interviews with the occupants of our panel of residential properties, about 3,350 households at each site. The households in this sample are chosen on the basis of characteristics of their residences rather than on the basis of their own characteristics; but from prior knowledge of the general distribution of households at each site by type of household and by type of housing, we are able to estimate the composition of the baseline household sample even though we do not strictly control it by our sampling procedures.

Table 4.10 summarizes our general expectations about the composition of the baseline panel of households at each site, by income and relationship to the housing allowance program. The figures are based on data for Site I.

*See Adele P. Massell, Compensating for Landlord Nonresponse in the Housing Assistance Supply Experiment, The Rand Corporation, WN-8268-HUD, June 1973, which explores ways of dealing with the most serious nonresponse problems should they occur.

**SOURCE:** Estimates by HASE staff from data reported by the U.S. Censuses of Population and Housing, 1970, for Site 1. See Massell, The Role of Household Survey Data in the Supply Experiment, Table 3 and related text. Components may not add exactly to totals because of rounding.

^Both eligible and ineligible.

Inasmuch as the panel of monitored properties is designed as a stratified random sample of all residential properties within the boundaries of the experimental site, its occupants constitute a stratified random sample of all households residing within those boundaries—with the qualification that bias could be introduced into the household sample as well as into the property and landlord samples when properties are excluded from the panel because of incomplete baseline survey records.

When this sample of households is viewed in terms of general experimental purposes—i.e., analyzing housing-market behavior in the context of a housing allowance program—its composition has substantial merits. It is divided almost equally among four groups that stand in different relation to the allowance program. One is the group of those...
who will actually be enrolled in the allowance program. The second is
the group of nonparticipants with annual incomes of under $7,000 who,
prior to the program, most directly competed with potential enrollees
for housing. The third is the group with incomes of between $7,000
and $10,000 who, after the program is under way, will compete most
directly with enrollees (now able to spend more) for housing. The
fourth is the group with incomes of $10,000 or more, who will be af-
fected by the allowance program only indirectly if at all.* Naturally,
our income intervals do not clearly separate these groups, but the
general configuration is clear.

Because of tenant turnover in our panel of residential properties,
the elements of this household sample will not be identical from year
to year. When we encounter a new occupant in a monitored housing unit
we plan to administer the baseline survey instrument, which includes
an extensive retrospective on residential mobility and associated cir-
cumstances of housing, family size and composition, income, employment,
and place of work. Despite tenant turnover, the sample of households
interviewed each year will still constitute a stratified random sample
of all households, provided that the sampling frame of residential
properties is updated each year to include newly constructed housing.

Since the allowance program may affect residential mobility, we
cannot confidently predict the rate of tenant turnover from preallow-
ance data. Generally, we expect that about 40 percent of the house-
holds interviewed in any given year will have moved before the next
annual survey cycle.** About one-third of the movers will have left
the metropolitan area; the others will have relocated within the
boundaries of our experimental sites.

Those who make local moves could be followed to their new homes
by our field interviewers. This step is not essential to getting

---

*This group (households with incomes of $10,000 or more) comprises
about half of the household population in our candidate sites; thus, we
devote about one-fourth of our household monitoring resources to house-
holds in the upper half of the income distribution.

**These figures are higher than general mobility rates in the U.S.
population because our sample is heavily weighted with renters, who
move more frequently than homeowners.
information on postallowance moving behavior and its housing consequences, inasmuch as those who move into our panel of monitored housing units will constitute a stratified random sample of all local movers. However, examination of the sample sizes required for the mobility analyses described in Sec. VIII suggests that we may need some data on those who move out as well as on those who move in. How many and which of the local movers should be tracked to their next residence each year is a decision that should be postponed until the end of the year's survey cycle, when we will know the number and the characteristics of those who moved out of monitored units during the preceding year.*

THE "COMPARABILITY PANEL" OF URBAN RENTER HOUSEHOLDS

As noted elsewhere, data from the various experiments sponsored by HUD as part of the Experimental Housing Allowance Program (EHAP) are to be combined for integrated analysis. This task has been assigned to the Urban Institute.

To meet the needs of this integrated analysis, HASE has been asked to monitor a panel of urban renter households who are eligible to participate in the allowance program at each site. These households are to be administered the tenant survey instrument used for residents of rental housing units in our own panel of residential properties. However, those who move subsequent to baseline are to be followed to their new addresses (if these addresses are within the experimental site) and reinterviewed there in subsequent annual survey cycles. If they have not enrolled in the allowance program within two years of baseline, or if they purchase a home, they are to be dropped from the panel without replacement.

The specifications for the panel reflect an attempt to construct a sample of households that is comparable to the sample of households

*Our initial analysis of this problem, reported in Massell, The Role of Household Survey Data, Sec. IV, was premised on lower estimates of mobility than we now expect. Given our plans for monitoring movers in the "comparability panel," discussed below, we do not now expect to follow additional households who move from empaneled properties.
enrolled in the Housing Assistance Demand Experiment (HADE), where program participation is limited to urban renters and where all participants are interviewed regularly for three years beginning with a baseline interview at the time of enrollment.*

Candidates for the comparability panel are to be selected from among households completing a regular HASE screening interview, but a candidate household will be admitted to the panel only if it also completes a baseline interview. Design specifications for the comparability panel call for about 800 empaneled households in Site I and 1,600 in Site II.** The difference in sample sizes for the two sites reflects an additional stratification by race in Site II, impractical in Site I because of the minuscule numbers of nonwhite residents there.

Since the regular HASE survey instrument is used in both cases, there is no impediment to assigning a household to both the HASE panel and the comparability panel, and there are obvious economies in doing so. We expect a substantial overlap of the two panels at baseline. However, the HASE panel is a panel of residential properties, and baselined households will be dropped from the HASE survey agenda if they move from an empaneled property; the new occupants of their former residences will replace them on the tenant survey schedule. Comparability panel members, on the other hand, will be followed if they move and will be interviewed at their new addresses.

In addition to interviewing households selected for the comparability panel, we have also agreed to complete residential building reports for their places of residence. For those who enroll in the housing allowance program, we will retrieve housing-evaluation reports as well. Landlords of comparability panel households will not be interviewed except for cases in which the household lives on a property that is included in the HASE panel.

* Enrollment in the HADE allowance program is by invitation only, based on sampling considerations.

** The Urban Institute's design targets are expressed in terms of baseline interview attempts: 944 in Site I and 1,888 in Site II. These targets assume a baseline nonresponse rate of 15 percent. The figures cited in the text are therefore the desired number of baseline completions.
We have no obligation to analyze data gathered for comparability panel members, but may nonetheless find occasion to do so. For some of our planned analyses of household behavior, increased sample size would be welcome even without linkage to landlord records. Our analysis of household mobility, based generally on data obtained retrospectively from residents of empaneled properties, may benefit from a sample of cases in which movers are actually followed. Finally, analysis of landlord nonresponse bias may be aided by an examination of tenant interviews and residential building reports for cases in which no interview with the landlord was attempted, in contrast to cases in which the landlord refused to be interviewed.

OTHER MONITORING ACTIVITIES

In addition to monitoring the records of the HAO and the neighborhoods, buildings, owners, and tenants of our panel of residential properties, we now plan several special-purpose surveys on a much smaller scale. We also expect that developments at each experimental site will prompt additional special-purpose surveys whose nature cannot now be anticipated. Finally, in addition to systematic field surveys, we have assigned a resident observer to each site to provide us with continuous informal observation of housing-market activity, community attitudes toward the allowance program, and related political developments.

Special-Purpose Surveys

We presently see possible needs for small field surveys relating to two special groups: housing-market intermediaries and households who do not participate in the allowance program.

Market Intermediaries. Section VII of this report describes our plans for analyzing the effects of the housing allowance program on indirect suppliers and market intermediaries. These plans call for annual interviews with all major mortgage-lending institutions at each experimental site (perhaps 10 to 20 institutions) to monitor changes in their lending policies and to obtain data on delinquencies, foreclosures, and voluntary surrenders. In addition, a sample of
firms writing residential property insurance in the community may be interviewed to find out about changes in underwriting policy and trends in losses. Finally, we may find it useful to interview samples of real-estate brokers, management firms, rental agents, or home-improvement contractors to investigate ways in which the allowance program has affected their policies and activities.

In all of these cases, the number of interviewees is small and the interviews can best be conducted by a single individual who is conversant with the research issues and the nature of the respondent's business. We expect to use members of Rand's professional staff (or consultants) as interviewers. While some quantitative data will be sought, open-ended probes into policies, operating procedures, and views of the housing market are expected to be more enlightening than the quantitative data. Thus, we do not plan elaborate survey instruments.

Nonparticipating Households. A particularly interesting group within the general population of households is those who are eligible for housing allowances but who either fail to apply or drop out of the program. At one time, we proposed to survey a sample of such households, in part to learn their reasons for not enrolling and in part to learn enough about their housing and budgetary circumstances to judge whether it is important from the standpoint of program objectives to recruit them into the program—and if so, what program or procedural changes would be likely to have this effect. Now, it is evident that adequate data on this topic can be obtained as part of our regular annual survey of residents of empaneled properties.

A postbaseline tenant instrument has been designed that includes a module on attitudes towards the housing allowance program. The questions on income and household composition, elsewhere in the instrument, will enable us to judge each respondent's eligibility status under current program rules and even to estimate his allowance entitlement if he were to enroll. A series of questions in the attitude module inquires into the respondent's awareness of the program and his dealings with the HAO. Depending on the respondent's relation to the program—whether he is enrolled, has tried to enroll but was found
ineligible, is aware of the program but has not applied, or is unaware of the program—there follows a series of probes into the reasons for his status and his attitudes toward the program.

These data can be matched, in the case of program applicants and enrollees, with their HAO records; and in all cases, with other survey records pertaining to the empaneled property on which they live. Thus, we expect to be able to set respondents' reports of their experiences with the program and their attitudes toward it in a rich context of information from other sources. This background will help us to interpret the respondents' views.

Ad Hoc Surveys. It is not hard to imagine experimental developments that will raise questions of fact, perhaps concerning the supply of eligible households, the representativeness of one of our samples, the vacancy rates for housing of particular kinds, the conversion of properties from one use to another—there are many possibilities. To answer such questions, we may need to design and implement field or telephone surveys on short notice.

We propose to maintain at each site a limited capability for such survey work, under the direction of the resident observer whose other functions are discussed below. This capability is most apt to be useful in the event that the experiment has an unanticipated but significant effect on some particular sector of the housing market or on some particular community or group. Rather than wait for an annual survey cycle, we will want to inform ourselves quickly about the measurable aspects of the effect so that plans can be adjusted accordingly.

Informal Monitoring

We have assigned a resident observer to each experimental site to provide a continuous flow of information on events not captured or not capturable by formal survey methods. It will be his responsibility to follow local economic and political developments and community sentiments about the housing allowance program and related matters. He will spend much of his time attending meetings of civic and other local-interest groups, reading local newspapers, following events at City Hall, and talking informally to individuals active in the local housing market as suppliers, intermediaries, and consumers of housing.
While the means by which the resident observer gathers information will be informal, his reporting will be systematic. His reports will serve to alert our research staff (and our local site manager) to developments requiring programmatic or research responses. We expect him to be an active contributor to the ongoing review and evaluation of the experiment.

The resident observer will be supported by a part-time staff that may be employed for special projects—ad hoc surveys, abstracting public records, etc.

OTHER DATA SOURCES

Not all the data needed for our analysis will be obtained by direct fieldwork or from MAO records. We expect to make considerable use of secondary data, gathered by others for other purposes, including local public records, local planning and economic studies, corporate records, and various kinds of data gathered by state and federal statistical systems and private firms. We cannot now catalogue these sources exhaustively for each site, but the likeliest possibilities are indicated briefly below.

Public Records and Local Planning Studies. We expect to rely on public records for a variety of data, including locations of public facilities (schools, shopping centers, police and fire stations, hospitals, parks and recreational facilities, transit routes); information on the types of public utility or service available in each neighborhood (electricity and gas distribution, water and fire hydrants, sanitary and storm sewers, garbage collection); land-use and zoning maps; and various social indicators such as small-area crime and fire statistics. These data will be assembled at baseline and updated annually.

In addition, local tax assessment records will be used in selecting and screening our panel of residential properties; each year after baseline, building permits and demolition permits will be analyzed to guide panel modification. Local planning office studies of neighborhoods or larger areas may provide helpful special-purpose information.
U.S. Censuses of Population and Housing. Although the most recent census (1970) precedes by nearly four years the baseline surveys at our first site, it is nonetheless the most comprehensive and detailed source of information available on local population and housing characteristics. We have already made extensive use of these data in designing our sample of residential properties and in estimating allowance program eligibility. We anticipate continued use of these data, primarily for independent checks on estimates made from our field surveys. While discrepancies are to be expected because of the increasing obsolescence of the census data, large discrepancies in numbers or compositions of households or housing-stock estimates should be the occasion for special investigation to account for the differences.

Bureau of Labor Statistics and Related Sources. Appendix D of this report explains our plan for constructing price indexes for services, labor, and materials used in the production of housing services at each experimental site. We expect to make use of the BLS's Area Wage Survey and its Wholesale Price Index. Data on construction costs and mortgage interest rates, however, will come from local and regional indexes compiled by private firms (the Boeckh Building Cost Modifier, Roy Wenzlick Research Corporation).
V. ORGANIZING THE DATA FOR ANALYSIS

In Sec. II, we listed the four major research topics that motivated the design of the Supply Experiment, and we outlined the proposed sequence of events at each experimental site, including monitoring activities designed to provide data bearing on each topic. Section IV described that monitoring program in greater detail, explaining the principal sources of data and the methods planned for data collection. Here, we describe our plans for organizing these data, showing how they will be compiled into systematic files that can be manipulated in various ways for research purposes.

As indicated in Sec. IV, the monitoring program will acquire data from the administrative records of the HA0; from field surveys addressed to a panel of residential properties, their neighborhoods, their owners, and their occupants; from smaller special-purpose surveys; and from reports by the resident observer. Data from the first two sources will be large in volume, regular in format, and interconnected in reference; they are the most amenable to statistical analysis and, at the same time, they present the most difficult management problems. It is with these data that this section principally deals, although brief attention is given to the smaller special-purpose surveys. Reports of the resident observer may be equally important as a source of insights and as signals of phenomena that have escaped more systematic data-collection procedures, but data from this source pose no particular problems of file management and are not discussed here. Neither do we discuss data from secondary sources, such as the U.S. Census of Population.

Our concern here is not with the mechanics of data-processing but with the principles we will use to organize the large data files to serve research purposes. * We first explain the content and organization of each master file that we plan to create, then show how these master

---

files can be used separately and jointly to create research files for particular purposes. Finally, we show how the data contained in each file relate to each of the major research topics to be addressed by the Supply Experiment. This last step serves as a bridge to the ensuing four sections, which present our current plans for analyses relating to each of these topics.

CREATING AND LINKING THE MASTER FILES

Presently, we expect to create about twelve separate master files, each designed to receive periodic data from a particular source, storing the data cumulatively for permanent reference. Three of these master files will be compiled from administrative records of the HAO; four will be compiled from annual surveys relating to our panel of residential properties. These two groups constitute our major files, presenting the most complex file-management problems. The remaining five minor files are either temporary in purpose (the screening survey used to select our panel of properties) or small in size, and present less of a management problem.

The HAO Files

Table 5.1 describes the three files that we expect to create from HAO records. Although the HAO record system has yet to be designed, certain kinds of data will clearly be needed for administrative purposes and are likely to be organized as indicated here. In any case, the data will be periodically transferred to Rand for research purposes and can then be reorganized if necessary.

Each of these files will be divided into unit records, one for each household ever enrolled in the program. All are longitudinal files; new entries will be added periodically to each unit record until the subject household is separated from the program, at which time its record is (at least temporarily) closed but remains in the file.

The first of these is an enrollment file, containing a basic description of each enrolled household, including its home address, size, composition, and income, and other information bearing on

<sup>2</sup>The file may also contain some units certified at the landlord's request.
eligibility. Recertification procedures will provide semiannual updates of household size and income for each unit record so long as the household remains enrolled. Changes of address will be entered as they occur, and other administrative actions may result in entries at irregular intervals. Updating in this and all other files described below will be done by adding entries to the appropriate unit record, not by replacing previous entries.

A separate file will probably be maintained by the HAO to record disbursement of allowance payments to enrollees whose housing has been certified as meeting program standards. Each record in this file will include the name and current address of the authorized recipient, the name and address of his landlord, the certification status and contract rent of his housing unit, and the amount of the allowance payment. Records will be updated monthly by the HAO to reflect administrative actions bearing on allowance entitlement, changes of address, etc. At less frequent intervals, copies of the updated files will be transferred to Rand for analysis.

A third file will be constructed from HAO housing-inspection records. These inspections provide the basis for housing certification, a prerequisite to actual disbursement of allowance payments. The housing unit must be reinspected and recertified annually; if the allowance recipient moves, the new unit must be inspected and certified. Thus, this file will contain a continuous history of each recipient's housing for the duration of his enrollment, with periodic information on the condition of the unit and of the structure of which it is a part.

Each of these three files will contain a unit record for each household ever enrolled, the identity of the household defined by the person who heads it. We expect the size of each file to increase over time as new households join the program; at the end of five years, there may be as many as 10,000 unit records in each.

Figure 5.1 is a schematic representation of the cross-sectional and temporal links among these three files. Unlike the panel survey files discussed below, the timing of entries in the different files is not synchronized, so that a cross-sectional link at a given point in time may relate entries that are nearly current with entries that are
Fig. 5.1—Cross-sectional and temporal linking of HAO records for one enrolled household.
up to a year old. Moreover, the cyclical entries on individual unit records are not synchronized even within a given file: The initial enrollment dates, hence annual recertification dates, will differ for each enrollee; the same is true of housing-certification entries.

Panel Survey Files

Table 5.2 describes the four major files we expect to create from annual surveys related to the panel of residential properties. The unit records of each file will be opened at baseline, with new data pertaining to the same unit added annually thereafter.

The smallest of these files is the one compiled from the survey of neighborhoods. The entire area of each experimental site will be divided into 50 to 100 bounded neighborhoods; a unit record will be opened at baseline for each neighborhood and updated annually by a mixture of direct field observation and data drawn from public records.

From the survey of residential buildings, a unit record will be opened for each residential property selected at baseline as an element of our panel. The unit record may include data for more than one building, when more than one is present on a selected property (tax parcel). In subsequent years, the configuration of buildings may change, or existing residential buildings may be demolished or converted to nonresidential use; however, the unit record will be maintained by annual entries from the survey of vacant and nonresidential properties (V/NRP).

Unit records will also be maintained in this file for the small baseline sample of urban nonresidential properties, likewise monitored annually by means of the V/NRP instrument. Finally, after baseline, we contemplate an annual sample of rural residential building permits, and new unit records will be opened for each property selected from this source.

Altogether, we expect this file to contain fewer than 2,500 unit records at the end of the five-year monitoring program—all those in the baseline panel plus the newly constructed rural homes added later.

The third file in this group will be compiled from the annual survey of landlords, with a unit record opened for the owner of each

SOURCE: MASE staff, survey designs and sampling plans.

<sup>a</sup> File includes approximately 200 records for nonresidential properties, with file entries at baseline and annually thereafter; if such a property is converted to residential use, it is thereafter included in the survey of residential buildings.

<sup>b</sup> File includes special entries for vacant properties, from the survey of vacant and nonresidential properties.

<sup>c</sup> For vacant properties, formerly owner-occupied, the file contains special entries from the survey of vacant and nonresidential properties.

<sup>d</sup> For sample structures with four or fewer housing units, occupants of all units will be interviewed; for larger structures, a maximum of six units will be surveyed.
rental property in our baseline panel. In the event of a change of ownership, data on the new owner will be entered in the same unit record. If a single-family rental house is sold to an owner-occupant, the landlord record will be closed and a new unit record opened in the tenant-and-homeowner file, described below; of course, appropriate identification of both records will enable them to be linked for analysis.

If the property has no tenants in residence at the time of an annual survey cycle, the vacant-property modules of theV/XRF instrument will be the source of the year's entries for this file.

We expect this file to contain no more than 2,200 unit records at the end of the five-year monitoring period. All unit records will have a complete baseline entry, this being a condition of sample selection; but in some subsequent years, we may be unable to locate the landlord, or he may decline to provide the information sought. Thus, some unit records will be incomplete.

The last file of this group will be compiled from data gathered in the annual survey of tenants and homeowners. A unit record will be opened at baseline for each housing unit that is to be monitored. For single-family houses, whether renter-occupied or owner-occupied, there will of course be a single unit record for each residential property. For multiple dwellings containing fewer than five housing units, there will be a unit record for each housing unit on the property. For larger multiple dwellings, there will be up to six unit records, each for a specific housing unit selected at baseline. Unit records for tenants and for homeowners will differ in format; for the latter, survey data to be collected include information parallel to that sought for landlords of rental properties.

In subsequent years, some residential properties will be altered in ways which may either increase or reduce the number of housing units on the property; thus, new unit records may be opened or existing ones closed. In ambiguous cases, as when two units are merged, the identity of the surviving unit will be that of the baseline unit containing the same kitchen; undoubtedly, situations will arise that require ad hoc decisions as to which unit records to continue and which to close.
The identity of a household occupying a monitored housing unit will be keyed to a particular individual designated on first interview as the household head; if that individual moves out or dies, the occupants will be treated as a different household, even though there may be common members of the old and new households. More frequent will be the case in which an entire household moves out to be replaced by another.

Whichever is the case, the unit record pertaining to the monitored housing unit will accept entries reflecting the change in its tenancy; first interviews with a given household will generally be broader in scope than subsequent interviews.

For owner-occupied homes and single-family rental houses, all unit records will have a baseline entry unless the housing units to which they refer were vacant at baseline; multiple dwellings will be accepted into the panel at baseline as long as at least one occupant responds to the tenant survey, so some unit records may lack baseline entries. In subsequent years, unit records for all classes of properties will sometimes lack entries, either because a housing unit is vacant or because the occupant fails to respond to the survey. For vacant single-family houses that were last occupied by their owners, we will try to find the current owner and administer the vacant-property modules of the V/NRP instrument. If a single-family home transfers from ownership to rental tenure or vice versa, the unit record will be continued for subsequent occupants.

We expect this file, including both tenants and homeowners, to contain fewer than 4,000 unit records at the end of the five-year monitoring program.

We plan to make considerable joint use of these four files in the analyses described in later sections. They will therefore be designed for easy cross-sectional linking, as illustrated in Fig. 5.2. Each property, landlord, and occupant record will include a neighborhood identification code, linking it to a specific neighborhood record. Each landlord and occupant record will also include a property identification code, linking them to the property and to each other. Thus, properties, landlords, and occupants can separately or jointly
Fig. 5.2 – Cross-sectional linking of panel survey records for one neighborhood
be grouped for analysis by neighborhood; or properties can be grouped by type of property, and a special working file created which abstracts pertinent parts of the neighborhood, landlord, or occupant file. Similar special files can be created for landlords or for tenants, each carrying selected information from the other files.

As illustrated in Fig. 5.3, these cross-sectional links can also be extended over time. Each unit record in each file will have annual entries, all synchronized within the time needed to complete the fieldwork for a given survey, so temporal linkage—e.g., for measuring annual changes in some variable, record by record—is built into the file structure. But it will also be possible by means of mutual identification codes to link a landlord-record entry for Time 1 to an occupant entry for Time 2, etc. This feature of the file opens the way for analysis of lagged interactions among the actors and events relating to a particular property or neighborhood.

---

**Fig. 5.3**—Temporal linking of panel survey records for one residential property
Linking HAO and Panel Survey Files

In addition to the links among the three HAO files and among the four panel survey files, we also expect to be able to link HAO records to panel survey records in a way that will enrich the analytical possibilities of both files.

When the HAO records are transferred to Rand, one step in our processing will be to compare the name and address of each allowance recipient and his landlord with the current occupant, landlord, and property records compiled from our panel surveys. When a match is found, we will add appropriate codes to the HAO records, creating permanent links between the two sets of files. In most such cases, the allowance recipient will be the occupant of a monitored housing unit, and we will have data on his household from the survey of tenants and homeowners. Occasionally, the allowance recipient will be the occupant of an unmonitored housing unit in a monitored multiple dwelling; then, we will have only a landlord and building record to match with HAO records.

As illustrated in Fig. 5.4, we expect that about 25 percent of our panel survey unit records can be linked in any given year to HAO records; or viewed from the other perspective, about 15 percent of all HAO records in any given year can be linked to panel survey records. The number of linked records should be in the vicinity of 800 to 1,000.

The analytical possibilities created by this overlap of HAO records and panel survey records are numerous. We can, for instance, compare HAO housing-inspection reports with our own survey of residential buildings and with housing-unit characteristics reported by the survey of tenants and homeowners. We can count the number of allowance recipients occupying a monitored multiple dwelling and track changes in this number over time, or tabulate sequences of recipients and nonrecipients in particular housing units or buildings. Most important, by stratifying on variables that are present in both HAO and panel survey records, we can generalize about allowance recipients and their housing circumstances in terms of variables recorded by one source, using the other source to estimate incidence of occurrence in the relevant population.
**Minor Files**

Table 5.3 describes five minor files that we expect to create from special-purpose surveys. Only the first of these, the screening survey, has been designed in detail. Of the other four, three relate to market intermediaries; data-collection efforts will begin at baseline, with annual updates thereafter. The survey of movers will not be conducted until the first annual survey cycle after baseline.

The largest of these files, and the first to be opened, will be the one compiled from the screening survey. There will be a unit record on each household residing in the presample of all residential properties. This data file will be used for the final selection of properties for the panel surveys; information from this file will also be used in setting allowance-program standards. This file will not be updated; it will contain only the data from the screening survey. The file will be organized so that it will be possible to link it with the panel survey files by comparing housing unit and property identifiers. Since not all screened properties were selected for the baseline panel, only a portion of the records in the screening survey file can be linked to the panel survey files.

**SOURCE:** HASE staff, survey designs and sampling plans.

<sup>a</sup> Instructors not yet designed.

<sup>b</sup> Maximum five-year accumulation, tracking each local mover to next residence.
The surveys of mortgage lenders, property insurers, and real-estate brokers will include unstructured and qualitative information. While we posit automated data files on each of these, it is not clear that all, or even most, of the information from these surveys will be amenable to the data-control and processing methods planned for the other surveys. The files are small, with from 10 to 50 unit records in each. Unit records will be opened at baseline and updated annually thereafter.

After baseline, we will maintain a file on households that move out of our panel of monitored housing units. This file will be compiled from the survey of movers and will contain data pertinent to the analysis of mobility. The format and sample design for this survey are not yet established, nor will they be required until a year after baseline. We estimate that some 1,500 to 2,000 unit records would accumulate over five years if all local movers were tracked to their next residence. This file can be linked with the tenant-and-homeowner file through the household identifiers. Thus data on each household in the movers file can be linked with data on these same households for the period of their residence in monitored structures.

**ORGANIZING THE DATA FOR ANALYSIS**

From the master files described above, we expect to create many temporary working files, each designed to serve some specific analytical purpose. Some of these working files may consist of data from a single master file; others will include data from several master files, linked by common identifiers such as household, housing unit, property, or neighborhood codes. Some working files will be strictly cross-sectional, containing only data referring to a particular point or period of time; others will be longitudinal, following particular units of observation over time. As we have tried to show, the structure of our master files is such as to allow considerable flexibility in organizing the data for analysis.

Sections VI through IX, below, describe our plans for analyzing these data. Each section deals with one of the four major research
topics to which the Supply Experiment is addressed: (1) supply responsiveness, (2) behavior of market intermediaries and indirect suppliers, (3) residential mobility, and (4) effects on nonparticipants. Each of these analysis plans relies on data from several of our proposed master files. Before proceeding to these topical discussions, we will try to give the reader an overview of the various uses to which data from each file will be put.

To provide this general perspective, it is, of course, necessary to suppress detail. Unit records in our major files may eventually contain several thousand distinguishable items of data; in the two largest files (the survey of landlords and the survey of tenants and homeowners), the entries for the baseline year alone can number up to 500 for each unit record. Furthermore, each survey instrument is likely to be modified for postbaseline survey cycles, so precise descriptions of unit-record entries for future years cannot now be given.

Our purposes here will be better served by grouping the data topically, as was done in Sec. IV for discussion of the major survey instruments. Such topics are listed in the stubs of Table 5.4 (for files based on HAO records), Table 5.5 (for files based on the four panel surveys), and Tables 5.6 to 5.8 (for files based on several special-purpose surveys).

Tables 5.4 and 5.5 each have four columns, one for each of our major research topics. In each column, we have attempted to indicate how data from each file will be brought to bear on this research topic, either as measures (M) of experimental results that are of direct interest, or as variables that help to explain (E) the experimental result in question. The format of Tables 5.6 to 5.8 is the same, except that only one research topic is listed for each. In other words, for each major research topic, we present a set of hypotheses whose general form is $X = f(E)$. The individual tables are not self-contained: the hypotheses "run" across all three tables, which must therefore be examined jointly.

* See Tables 4.1 to 4.6 of Sec. IV, where the kinds of data included under each topic are described systematically.

SOURCE: HASE staff, preliminary concepts of postbaseline "attitude" modules, survey of tenants and homeowners.

NOTE: Modules similar to those indicated will be administered to indicated subsamples of all households living in monitored housing units in each postbaseline survey cycle. Topics covered must be considered in conjunction with "regular" modules of the survey of tenants and homeowners, shown in Table 5.5 for baseline instrument.

Entries in the table indicate the nature of the relationship: M = measures of dependent variables, E = explanatory variables.
Our analysis plans for each major research topic entail seeking answers to several distinct, if related, questions. Thus, there is not a unique $K$ for each major research topic; the several $M$s shown in each column in some cases indicate different kinds or sources of data that will be combined into a single measure of an experimental result and in other cases indicate measures that are individually of interest. Similarly, in addressing different questions within a major research topic, different groups of indicated explanatory variables will be appropriate. Finally, some kinds of data appear as measures ($X$) in one context but as explanatory variables ($Z$) in another.

Although perusal of these entries will provide the reader with a general idea of the logic of our analyses—i.e., what is to be explained by what—the explicit hypotheses cannot be adequately represented in this summary fashion. For a clearer understanding of the specific research questions to be addressed, the variables entailed in each, and the technique of analysis, we refer the reader to the four analysis plans presented in subsequent sections of this report. For more detail as to the specific data to be used in these analyses, the survey instruments themselves must be consulted. Here, we only want to show the extent to which each analysis plan draws on the different data files, and the extent to which a given class of data serves multiple analytical purposes.

**Analysis of Supply Response**

Our analysis of supply response to the experimental housing allowance program will draw both on HAO records (Table 5.4) and on records of the four panel surveys (Table 5.5).

To measure supply response, we rely primarily on the survey of landlords for rental properties and the survey of homeowners for owner-occupied properties to provide data that reflect changes over time in expenses related to the provision of housing services (to the market or to the owner-occupant). These measures ($X$) are supplemented by direct observation (survey of residential buildings) and occupant reports (survey of tenants and homeowners) of changes in the physical characteristics and condition of panel properties; for housing occupied by
allowance-program participants, similar information can be obtained from HAO housing-inspection records, some of which can be linked to panel survey records.

Explaining supply response entails two general lines of analysis: (1) determining the market stimulus provided by the allowance program and estimating the impact of this stimulus on market rents and rental revenues; and (2) explaining variations in supply responses among residential properties with different physical characteristics or locations or with different kinds of tenants or owners. Analysis of the first kind draws on HAO enrollment and disbursement records for data on the stimulus (P) provided by the allowance program generally and its specific incidence within the market; and on the landlord and tenant surveys for data on changes in market rents and rental revenues in various sectors of the market. Analysis of the second kind draws on all four panel surveys for neighborhood, building, landlord, and tenant characteristics (Z) that may affect supply responses.

Analysis of Market Intermediaries and Indirect Suppliers

Here, we are interested generally in allowance-related changes in the policies and activities of those who supply mortgage capital, insurance, management or brokerage services, and residential repairs and improvements; and in impediments to the success of the allowance program resulting from shortages of these services or to the inefficiency or restrictive policies of those who provide them. However, our research is not guided by strong prior hypotheses; we think these will emerge only as we monitor the allowance-stimulated market.

For baseline, at least, our analytical objectives are essentially descriptive, following two lines: (1) to learn how the services of market intermediaries and indirect suppliers are used by different sectors of the housing market, and (2) to learn how the industries themselves are organized and how their decisionmakers view the market.

The first purpose will be served principally by data drawn from the panel surveys (Table 5.5), where data (X) will be collected on mortgage financing and insurance, the use of management firms, rental agents, and real-estate brokers, and the use of contract services for
maintenance, operations, repairs, and improvements; variations in utilization can be related to characteristics (e.g.) of the neighborhood, the building, the landlord, and the occupants.

The second purpose will be served by small-scale and informal (but systematic) surveys of members of the relevant industries. Table 5.5 describes the tentative contents of three such surveys--of mortgage lenders, property insurers, and real-estate brokers. We expect to assemble data on other such industries (e.g., home-repair contractors) from secondary sources and to monitor them informally; however, we may at some point determine a need for systematic field surveys.

Analysis of Residential Mobility and Neighborhood Change

Our interest here relates to changes in the frequency and pattern of movement that result from the allowance program and its long-run implications for the residential distribution of program participants and others.

For allowance-program participants, HAO records (Table 5.4) provide us with a complete account of their residential distribution at any point in time and of their moves over time (H), as well as considerable information about participants and their housing, which may partly explain (E) observed mobility or lack of it. And a subset of these records can be linked to the four panel surveys (Table 5.5), providing a bridge to broader analyses of marketwide mobility patterns.

In the latter table, the survey of tenants and homeowners includes a mobility retrospective to capture preallowance residential choices and mobility data (H) for all occupants of monitored structures, some of whom will (after baseline) enroll in the allowance program. We will seek to explain (E) their behavior by a coordinate history of household characteristics, income, and employment, and neighborhood characteristics of their successive residences. Their current housing and neighborhood circumstances, of course, play a role in explaining both their most recent moves and their next moves, the latter to be observed in subsequent survey cycles.
Table 5.7 describes the tentative contents of a survey instrument to be administered in postbaseline years to a sample of households moving from monitored housing units to other local addresses. In addition, those who replace these movers in our panel of monitored housing units will provide mobility histories for both preallowance and postallowance years.

Analysis of Effects on Nonparticipants

Although our research charter indicates a special interest in the effects of the allowance program on nonparticipants' housing circumstances and on their attitudes toward the allowance program, we (and, presumably, HUD) have an equal interest in these same issues in the case of program participants. In general, program effects on nonparticipants will be mediated or reflected by supply response in relevant market sectors; by the terms and policies of market intermediaries with whom nonparticipants must deal; and by allowance-induced mobility and related changes in patterns of residential location. Those issues can best be analyzed (for both participants and nonparticipants) by disaggregation of data already discussed under those headings. The most distinctive element of this portion of our charter is the interest in attitudes toward the allowance program.

Entries in the last column of Table 5.4 reflect our presumption that the characteristics, housing and locational choices, and housing expenditures of allowance-program participants will help to explain (\(E\)) both the effects of the program on the housing circumstances of nonparticipants and nonparticipants' attitudes toward the program. In Table 5.5, we have endeavored, awkwardly, to reflect the double role of most of the panel survey data, as measures (\(M\)) and as explanations (\(E\)) of either effects or attitudes.

Table 5.8 details the tentative contents of modules to be added in later years to the household survey instrument (survey of tenants and homeowners) whose baseline contents are described in Table 5.5. Here, we have divided respondents into three classes: program participants, eligible nonparticipants, and ineligible nonparticipants.
For each group we expect to probe for attitudes toward the allowance program (M) after inquiring into factors (F) that we expect will have a bearing on attitude formation. These factors, of course, include material covered by the "regular" modules of the instrument, described in Table 5.5.

Summary

We suspect that, for most readers, the preceding sketch of relationships between our data files and the analyses we plan to conduct raises nearly as many questions as it resolves—partly because the contents of each file are so laconically described, and partly because the research topics and methods of analysis are so briefly treated. In constructing Tables 5.4 to 5.8, we were not infrequently forced to make arguable decisions—whether to balance a particular kind of data could more intelligibly be represented as measures of effects (K), or as explanatory variables (F), or as both. We suggest that individual entries in these tables should not be taken too seriously; our purpose here is only to show generally how our various sources of data will be brought together in analysis.

Sections VI through IX, following, describe in more detail the analysis plans for each major research topic, elaborating on the specific questions to be addressed, on the data pertinent to each, and on the appropriate analytical methods. Readers of these sections may perhaps profit by referring back to the tables and figures in this section and in Sec. IV to confirm whether provision has been made for gathering and storing the necessary data, whether appropriate links can be made between data for different entities, data from different sources, and data gathered at different points in time, and whether the sampling frames and sample sizes are appropriate to the issues.

* We assume here that our panel survey of tenants and homeowners will include enough members of each group to provide an adequate sample for attitude analysis. As noted in Sec. IV, we may find it expedient in postbaseline years to separate attitude surveys from the panel survey of tenants and homeowners, or to supplement the panel sample where it is thin.
VI. ANALYZING SUPPLY RESPONSE TO HOUSING ALLOWANCES

POLICY ISSUES AND RESEARCH QUESTIONS

As its name suggests, a principal aim of the Supply Experiment is to determine how the suppliers of housing services respond to an increase in effective demand—specifically, to an increase in the effective demands of low-income households brought about by conferring on them some form of housing allowance.

The purpose of such an allowance would be to enable low-income households to consume a larger quantity of housing services without decreasing their consumption of other commodities. At least from the perspective of housing objectives, the overall measure of program efficiency would be the increase in the quantity of housing services consumed per dollar of housing allowance. Maximum efficiency would be achieved if (1) housing expenditures increased by the full amount of the allowance, and (2) there were no increase in the price per unit of housing services.

Finding a way to approach the first type of efficiency goal is the central purpose of the Demand Experiment, which will test various allowance formulas and various earmarking provisions to discover how housing expenditures change as a result of the allowance. The Supply Experiment is concerned with the second goal. Many observers, including some who support the principle of subsidized housing for low-income families, have argued that a national program of housing allowances would be an inefficient, perhaps even ineffective, means of achieving better housing for the recipients—that increased spending by low-income families for housing services would force the price of these services upward, so that the benefits conferred on the assisted families would be in part or wholly wasted. Moreover, if such price increases also affected the housing services purchased by unsubsidized families, whatever gains were made by the assisted low-income families would be substantially at the expense of the unsubsidized families—particularly those whose incomes were just above the level of eligibility for housing allowances.

To address these concerns, the Supply Experiment should be designed
to yield reliable estimates of the changes over time in the prices and quantities of housing services consumed by both subsidized and unsubsidized households in an allowance-stimulated market. *Manifestly, these changes will reflect characteristics of the allowance program that serves as a stimulus to the market: the number of participating households, their characteristics, the amounts of their allowances, and the restrictions imposed on their use of the allowances. But whatever the details of the allowance program, its pertinent consequence will be a known increase in housing expenditures within the experimental site. Our task is to determine how these increased expenditures translate into price changes and changes in the quantity of housing services provided by the market.

It is obviously necessary to choose a specific allowance program for the Supply Experiment. It would be preferable, but obviously impossible, to choose the as-yet-undesigned national allowance program. In lieu of that inaccessible alternative, we propose one which would be plausible in the light of the objectives of a national housing allowance program and which also has desirable characteristics from an experimental point of view. Chief among the latter is that the proposed experimental allowance program is designed to cause a substantial increase in housing expenditures by a large number of recipient households, both renters and owners. **

Our measurement objectives are twofold: First, we want to measure the price and quantity changes that actually occur at our experimental sites, distinguishing as well as we can between changes attributable to the experimental allowance program and changes attributable to background events that are independent of the allowance program. Second, we want to estimate typical responses of suppliers in different sectors of the market to changes in demand from whatever source. These

---

*Our general analysis of supply response, presented in this section, relates both to allowance recipients and to nonrecipients. Effects of the allowance program on nonrecipients are also discussed in Sec. IX.

**See Sec. III for a description of the experimental allowance program.
response parameters can then be linked analytically to other configurations of demand changes, in order to estimate the supply responses at our experimental sites to allowance programs that differ from the one actually employed there; and also to estimate supply responses to specified demand stimuli in housing markets other than our experimental sites.

We think that the first of these two objectives has prior importance. Unless we are able to provide a convincing account of supply response at the experimental sites, analytical generalizations from our data will carry little weight. The latter, in any case, are subject to important qualifications, discussed in Sec. X.

The analysis plan described below, therefore, addresses four responses to events at our two experimental sites:

1. The amount by which the supply of housing services increases following the introduction of the housing allowance program.
2. The amount by which the average price per unit of housing services increases following the introduction of the housing allowance program.
3. The extent to which these changes are attributable to the allowance program, as distinguished from other factors.
4. The response of suppliers in different sectors of the market to changes in the demand for housing services in that sector.

THE EXPERIMENTAL STIMULUS

The experimental housing allowance program described in Sec. III will alter the housing demands of recipients by (a) increasing their incomes and (b) compelling most of them to increase their consumption of housing services. From administrative records of the allowance program, we will be able to determine with precision how much is disbursed in the form of housing allowances. Enrollees will also be required to report their housing expenditures at the time of enrollment, and periodically thereafter. Thus, except for misreporting, we will be able to determine how much the allowance program has directly added to aggregate housing expenditures within the experimental site.
Housing expenditures by those not enrolled in the allowance program may also change during the course of the experiment. Our program of household surveys will enable us to estimate reasonably well the aggregate changes in the numbers of nonrecipient households and the aggregate changes in housing expenditures by nonrecipients. These estimates will not be as accurate as those for recipients because they will be based on sample data, and sampling rates in some sectors of the housing market will be low; on the other hand, we have a priori reason to expect substantial changes in nonrecipient expenditures.

Thus, from allowance-program records and from our sample survey of households, we will be able to estimate the aggregate change in housing expenditures within the experimental site at annual intervals following introduction of the housing allowance program; we will also be able to decompose this total into the amount attributable to allowance recipients and the amount attributable to nonrecipients.

These observed changes in housing expenditures are not the same as changes in the demand for housing services. Even with no change in demand, events on the supply side of the market could result in a change in the price of housing services that would in turn lead consumers to spend either more or less for housing. The distinction between a change in expenditure and a change in demand is important when we attempt the analytical integration of data from the Supply and Demand Experiments. But for present purposes we do not need to know whose demand schedules have shifted, or why; we only need to know by how much housing expenditures have changed, and what part of the total change is directly attributable to allowance recipients.

MEASURING SUPPLY RESPONSE TO A CHANGE IN HOUSING EXPENDITURES

The central technical problem of measuring supply response is to find a way to disentangle changes in the price of housing services from changes in the delivered quantity of such services. Even in a controlled experimental context, the only readily observable magnitude pertinent to this problem is the change in housing expenditures. By definition,

\[ A = E_{q} \]  

(6.1)
where $\hat{y}$ = housing expenditures (e.g., rental payments);  
$P$ = price per unit of housing services; and  
$Q$ = number of units of housing services delivered.

An increase in housing expenditures is an expectable and intended consequence of a housing allowance program and does not in itself cast any light on whether housing consumption or housing prices have increased. However, if we know $\Delta y/P$ and can find a way to measure $\Delta Q/Q$ directly, then $\Delta Q/P$ can be observed as a residual.

Alternative Measures of Quantity Changes

There are three general approaches to the measurement of $\Delta Q/Q$, each suffering from both conceptual and practical difficulties:

1. Observing changes in the quantities of physical inputs to the production of housing services.
2. Observing changes in the quantities of physical outputs from this production process.
3. Observing changes in tenants' satisfaction with the housing services they consume.

The second of these methods would fit most neatly into the machinery of market analysis, which is designed around the concept that the output of a production process is a tangible physical commodity which can be divided into homogeneous, easily counted units. Housing services do not fit this description very well; although we can easily count the number of separate living accommodations, the number of separate rooms, or even the number of square feet of floor space in a housing inventory, these measures clearly do not capture all that we mean by "housing services." Obviously, a tenant would not be indifferent between two apartments that were identical in these respects but differed in design, decoration, level of maintenance, building services provided, or location.

At the very least, measuring changes in the output of housing services would require a multidimensional scorecard, one that would almost certainly be incomplete in the number of dimensions. Furthermore, even among well-defined dimensions, some cannot readily be measured on a
cardinal scale (e.g., "amount" of interior decoration), and there is no readily available weighting scheme to aggregate changes along the various dimensions. At best, one could select a subset of housing characteristics that were readily measurable on cardinal scales and assume that the remainder were collinear with those measured.

Indeed, any serious attempt to measure the flow of housing services leads inevitably to either the first or third approach. Thus, counting housing units or rooms is really counting the structural capital which contributes, along with other physical inputs, to the current flow of services. Attempting to aggregate across output dimensions leads to weighting schemes (such as hedonic indexes) based on consumer preferences expressed in the marketplace. For our purposes, such weighting schemes have the conceptual defect that there are alternative sets of weights, depending on whose preferences are being considered, and the operational defect that construction of hedonic indexes that are sensitive enough to distinguish any except gross changes in price from concurrent changes in the flow of housing services has never been achieved and may not be achievable.

The third approach, directly measuring consumer satisfaction, suffers from several difficulties. To be sure, tenants may be interviewed and asked whether their housing has improved, either along specific dimensions, or in general. When the same tenant living in the same housing unit responds differently at two successive interviews, that is prima facie evidence of an ordinal change in his housing conditions. It would be much more difficult to devise an interview technique that yielded the cardinal measures ("How much has your housing improved?") that would be needed for analysis of any subtlety; and given the diversity of tastes among consumers, the commensurability of their responses (e.g., responses of successive tenants of a given housing unit) is very much in doubt.

For the Supply Experiment, we propose measurements both of changes in the physical characteristics of our sample of residential structures and of changes in the housing satisfaction of their tenants. Prior to the commencement of the allowance program, each residential structure in the sample will be surveyed; its basic physical characteristics,
appliances and equipment, and interior and exterior condition will be recorded by a combination of direct observation and tenant interviews; annual resurveys will record the same information by the same methods. Similarly, tenant attitudes toward the housing unit, the structure, the landlord, and the neighborhood will be recorded at baseline and annually thereafter.

While these data should enable us to detect changes in specific features of a structure or dwelling unit, they do not readily combine into an overall measure of the change in total quantity of housing services delivered by the structure or unit. Without such an overall measure, it is obviously difficult to reach unequivocal conclusions about accompanying price changes except under special circumstances.* For that purpose, we must turn to the first approach suggested above, observing changes in the quantities of factors used in the production of housing services.

**Measuring Changes in Factor Inputs**

This approach has several advantages. First, we can come much closer to comprehensive measurement of inputs than of outputs or of consumer satisfaction. Second, cardinal measurements are possible. Third, different kinds of factor inputs can be combined into a single aggregate measure by means of a deflated-price weighting scheme whose properties are well understood. Finally, if measuring changes in inputs does not tell us precisely how much output changed, it at least tells us how hard the producers tried to change outputs.

Briefly, the measurement scheme would work as follows:

1. Inventory all expenditures (explicit and implicit) for factor inputs during the year preceding the beginning of housing allowance payments (V).

*Where annual resurveys show only trivial changes in physical characteristics, appliances and equipment, and interior and exterior condition, a change in rent is manifestly a change in price. But we have no assurance that this special case will occur with enough frequency to serve as a basis for statistical inference.
2. During the experiment, record changes in expenditures for factor inputs measured in current dollars, cumulating these over a comparable time period, and deflating the totals to base-year dollars by factor-specific price indexes (Δ\(\Pi\)).

3. Calculate the ratio of the change to the base (Δ\(\Pi/\Pi\)); take this change as a measure of the change in output (Δ\(\omega/\omega\) = Δ\(\Pi/\Pi\)).

4. Record rental revenue (\(\mathcal{R}\)) for the year preceding the beginning of allowance payments.

5. During the experiment, record annual changes in rental revenue (Δ\(\mathcal{R}\)).

6. Using the relationship

\[
\frac{\Delta \mathcal{F}}{\mathcal{F}} = \frac{\Delta \mathcal{P}}{\mathcal{P}} + \frac{\Delta \mathcal{C}}{\mathcal{C}} + \frac{\Delta \mathcal{P} \Delta \mathcal{C}}{\mathcal{P} \mathcal{C}},
\]

(6.2)

estimate the relative change in the price of a unit of housing services as a residual.

An alternative to Step 2 would be to reinventory all factor inputs and derive the change by differencing against the base-year inventory. The objection to this alternative is that major items in base-year factor expenditures are the annual costs of land and structural improvements, i.e., their market values multiplied by the current market rate of interest. These market values may change in the course of the experiment for various reasons, such as a shift in the demand for housing services, and we have no price index to deflate them. Furthermore, differencing two magnitudes neither of which can be measured with great precision yields an extremely imprecise estimate of the change if the difference is small relative to the base.

On the other hand, it appears to us that nearly all the significant changes in capital and current inputs can be captured by event recording. These changes include land and existing buildings converted to or withdrawn from residential use, valued at base-year appraisals; new construction and alterations to existing structures, valued at cost of production and deflated to baseline values by a construction cost...
index; and current maintenance and operating outlays, deflated by factorspecific cost indexes. The explicit procedures are detailed in Appendix B.

The Relationship Between Input Changes and Output Changes

The most serious objection to our procedure is the possibility that it may overestimate changes in the quantity of housing services produced and underestimate changes in the price of those services. The reasoning behind this objection is simple and forceful: For many production processes in which output is readily and directly measurable, a short-run change in the level of output can be shown to reduce the technical efficiency of the production process. Contrary to our assumption above, the change in output is less than proportional to the change in factor inputs ($\Delta q / q < \Delta u / u$).

If this rule applies to the production of housing services, we would like to know about it, yet it cannot be directly tested without an independent, reliable measure of the physical quantity of output—which, we have argued, is inaccessible. But all is not lost. We have devised a method for analyzing changes in factor inputs and rental revenues for individual buildings that yields an estimate of the typical elasticity of output to changes in inputs that occur during the experiment. The method relies in part on the existence of variations among buildings with respect to factor-input changes, and in part on the assumption that both factor prices and output prices are more or less uniform throughout the universe of buildings covered by the analysis.

If this analysis succeeds, its findings can be used to adjust our estimates of relative changes in the price and quantity of housing services delivered during the course of the experiment. We suspect, however, that the initial circumstances of the housing stock in the modular neighborhoods are such that our assumption ($\Delta q / q = \Delta u / u$) will be approximately correct.**

---

*See Appendix C.

**Our reasoning is presented in Appendix B.
Estimating Changes in the Price of Housing Services

Having directly observed relative changes in housing expenditures ($\Delta z/z$), and having estimated relative changes in the quantity of housing services supplied to the market ($\Delta q/q$) by the procedure described above, it is then a simple matter to calculate the relative change in the price of a unit of housing services between the base and test years; rearranging Eq. (6.2), we have

$$\frac{\Delta p}{1} = \left( \frac{\Delta z}{z} - \frac{\Delta q}{q} \right) \left( 1 + \frac{\Delta c}{c} \right)^{-1}.$$  \hspace{1cm} (6.3)

The Unit of Analysis

The analytical plan described above relies on measurements taken on a sample of individual residential properties. For each such property, our annual field surveys will compile the data needed to estimate annual rental revenue for rental structures and annual housing expenditures by homeowners.* For each such property, these surveys will also provide the data needed to estimate the quantity of factor inputs required to supply these housing services. The calculations summarized in Eqs. (6.1), (6.2), and (6.3) can thus be performed for each of the structures in our sample, leading to estimates for each structure of the relative changes in rental revenue for that structure, in the quantity of housing services it supplies, and in the price per unit of those services.

We do not expect these changes to be uniform throughout the sample. Different sectors of the housing stock will be differently affected by the allowance program, and the owners of individual buildings will respond differently to market signals which they may also perceive differently. Rental revenues in some structures may increase, while in others they decrease. Some landlords may improve their buildings,

*The analysis in the case of homeowners differs in important respects from that for rental property. The differences are discussed later in this section.
others may withdraw them from the market.* These differences—in impact, by market sector, and in response, by characteristics of structure or of landlord—are of considerable interest and are discussed later in this section. Here, however, we are concerned with the overall effects of the housing allowance program on the flow and price of housing services in the experimental sites.

To estimate the aggregate change in the supply of housing services between baseline and each annual survey cycle, we must generalize from our sample. Although the sampling rate will vary by market sector, it will be known for each sector, and we can attach weights to each observation reflecting its sampling rate. Summing the weighted observations of revenues and factor inputs across the sample, we can estimate inter-period changes in total housing expenditures and decompose them into changes in quantity and changes in price, using the same technique as for an individual property.

As noted in Sec. IV, our baseline survey will include a sample of parcels of urban land not then in residential use; if some of these parcels are subsequently converted to residential use, our annual surveys will capture them as additions to the supply of housing. Outside the urbanized area, we propose to sample residential building permits annually to estimate additions to supply from new construction. Also, among our original panel of residential structures, some will be withdrawn from residential use in the course of the experiment; these events too will be captured in our annual surveys.

Thus, within the limits of sampling error, we expect to be able to estimate aggregate changes in the flow of housing services and average changes in the price per unit of housing services. If we succeed in this task, the remaining problem is to determine what parts of these changes are attributable to the housing allowance program and what parts to other factors.

---

*For a scenario of market response, see Lowry, Rydell, and de Ferranti, op. cit., WN-7711-UI, Sec. IV.
Decomposing Changes in Housing Expenditures

Appendix B presents a method for decomposing an observed change in housing expenditures into seven component parts. We are able to identify shares of the total increase in housing expenditures (or rental revenues) attributable to changes in

a. Real-estate taxes;
b. The quantity of factor inputs;
c. The market rate of interest;
d. Prices of capital-improvement inputs;
e. Prices of maintenance and repair inputs;
f. Prices of building-service inputs; and
g. Producers' markup on factor costs.

This decomposition is an extremely important part of the analysis of the results of the Supply Experiment. It enables us to distinguish the share of the change in total expenditures that reflects a change in the flow of housing services (or at least of real factor inputs) from the share that reflects only price changes; and among the components of price change, it enables us to distinguish those that benefit the supplier from those that are simply passed on by him to the consumer.

Thus, the direct beneficiary of Share (a) is the municipal fisc; in a national program of housing allowances, the resulting increase in real-estate taxes would be considerable—on the order of 15 to 25 percent of the increase in housing expenditures—unless effective tax rates on market value were lowered.

Share (b) is the only direct benefit that accrues to tenants. Strictly speaking, it is the increase in the quantity of resources used to produce housing services; subject to the qualifications presented earlier, it also measures the increase in the flow of housing services during the course of the experiment.

Share (c) in our accounting scheme accrues to the owners of residential property until such time as they refinance their mortgages or incur new indebtedness. Changes in the market rate of interest may be either positive or negative, depending more on events in a much broader
capital market than on the housing allowance experiment. Under a national program of housing allowances, it is possible that increased demand for mortgage funds would drive up the market interest rate. The experiment will enable us to estimate the magnitude of this increased demand for mortgage funds; others, versed in the lore of national money markets, could do better at estimating the effects on the interest rate.

Shares (d), (e), and (f) benefit neither the producer nor the consumer of housing services. Depending on the scale of our experiment, these price changes may be purely extraneous events—"background inflation" in response to regional or national influences—or they may be partly caused by the experiment itself.

Our a priori calculations lend little support to the notion that the increased factor demand due to the experimental allowance program will be large enough to influence factor prices perceptibly, even though the allowance program embraces an entire metropolitan area. However, we propose to monitor local factor prices and compare their changes with corresponding changes reported in regional and national indexes.

Finally, Share (g) is a residual, the difference between the change in rental revenues and the change in the cost of production of the housing services delivered. This residual, which may be either positive or negative, accrues to the owners of residential property. Under conditions of increased demand, we would expect Share (g) to be positive. With qualifications, it may be described as the payment needed to persuade producers to increase factor inputs by the observed amount.

Overall, the responsiveness of housing supply to the observed increase in housing expenditures can be judged simply by the magnitude of Share (b)—i.e., by the percentage of the incremental housing expenditure that went for real increments of output. A more discriminating judgment, however, would certainly net out background inflation and fiscal recapture through real-estate taxes—leaving only demand-caused inflation in factor prices and changes in owners' profits as relevant inefficiencies.

*See Appendix D for details.
Netting Out Background Effects

Above, we have discussed a logically tight method for decomposing the observed changes in housing expenditures into shares attributable to real-estate taxes, payments for increased housing services, several kinds of factor-price changes, and changes in the producer's markup on his costs. This decomposition brings us considerably closer to an understanding of the supply response to the experimental allowance program, but there remains a problem of imputing observed price changes to specific causes. This cannot be done with precision, but we think it can be done adequately for our purposes, unless the experiment is conducted in a very unstable market environment.

Items (c) through (f) of our decomposition are factor-price changes—changes in interest rates and in the costs of capital improvements, maintenance and repairs, and building services. Although such changes are most likely to reflect market forces on a regional or national level, they could also result from local forces: an allowance-induced increase in demand for housing services, changes in housing demand by nonrecipients, or even in some cases, competing demands by other users of these factors of production (e.g., commercial construction). Item (g), the housing producer's markup on factor costs, is unlikely to be affected by forces other than those in the local housing market, allowance-induced and otherwise.

Accounting for nonlocal inflationary forces is easiest. We plan to construct local price indexes for factors used to produce housing services; these can be compared to corresponding price indexes for the region within which our experimental site is located. We seriously doubt that after discounting the nonlocal effects there will be much left in the way of factor-price changes to account for, unless the experimental housing allowance program coincides with a local building boom.

Sorting out allowance-induced and other local demand pressures on factor prices and (more important) on producers' markups is more complicated. The experimental allowance program is a deliberate-demand

* See Appendix D.
stimulus, controlled in amount and measurable in its effects on housing expenditures. As noted earlier, our monitoring program will provide us with the basis for fairly good estimates of changes in non-recipient housing expenditures, especially in those sectors of the housing market where nonrecipients compete with recipients. We will also be able to estimate changes for nonrecipients in the principal factors affecting housing demand, i.e., numbers of households and household incomes.

The influence of these independent changes on the demand for housing services within the experimental site can be estimated, provided that the price and income elasticity of the demand for housing is known. Similarly, the supply response to these nonrecipient demand changes can be estimated if the price elasticity of supply and the amount of any exogenous factor-price changes is known.

In principle, the necessary data and parameters will be available to calculate the price and quantity of housing services that would have cleared the market in the absence of the allowance program. Our monitoring program measures the forces affecting demand and also the non-local factor-price changes. The Demand Experiment is designed to provide estimates of the income and price elasticities of the demand for housing services. As described later in this section, the Supply Experiment is designed to provide estimates of the price elasticity of the supply of housing services. The mathematics of the general solution to our problem are developed in Appendix E.

Though the data needed for such an analysis are all scheduled to be produced in some form within the general framework of the Experimental Housing Assistance Program, their uneven quality and the complexity of the implied econometric modeling do not encourage us to think of this procedure as a means of netting out second-order background effects. If our annual surveys reveal only minor changes in the numbers and incomes of nonrecipient households, we doubt that going

*Changes in the number and incomes of nonrecipient households will not be entirely independent of the allowance program. Between allowance payments and local expenditures for monitoring, the experiment will pump $5 million to $10 million annually into the local economy.
through such an analysis would add much to our understanding of the effects of the experimental allowance program on the local housing market.

At the other extreme, there are possibilities of major shifts in nonrecipient housing demand due to rapid growth or decline in the local population or drastic changes in income, events that might occur because of a severe dislocation in the metropolitan economy. Should such dramatic events occur, producing a change in nonrecipient housing demand that is large relative to the allowance-induced change, we doubt that any formal analysis would salvage a credible interpretation of the effect of the allowance program on the local housing market.

The useful analytical possibilities lie between these extremes, for experimental outcomes in which changes in nonrecipients' housing demands appear to be comparable in magnitude to the changes induced by the allowance program. We believe that our monitoring program will provide us with the data needed to assess the approximate responsibility of the allowance program for observed increases in the price of housing services and in the prices of the factors used to produce those services.

Is Vacant Housing Part of the Supply?

At any given time, some housing units within our experimental site will be unoccupied—probably 3 to 7 percent of the total. Over time, the number of vacancies and the particular units that are vacant will change. Our plan for measuring changes in the flow and price of housing services must deal with these vacant units: Should they be counted as emitting housing services? If so, who pays for these services?

It is possible to construct alternative models of a housing market that handle these issues differently. We think that the purpose of the present analysis—measuring the marketwide supply response to a permanent change in housing demand—is best served by including vacant units as part of the supply, so long as they are available for sale or rent. And in calculating the price of housing services, we propose to count only actual receipts from the sale of housing services, net of vacancy and collection losses.*

*The special problems of pricing owner-occupied units are discussed later in this section. The discussion that follows presents the issues in terms of rental housing.
This system of accounts is designed to reflect the supplier's rather than the consumer's view of the housing market. A tenant pays a contract rent, in return for which he receives a bundle of services and amenities. His view of the price of housing services is formed by comparing the rent he pays to his perception of the "size" of that bundle, its elements weighted in terms of his preferences.*

The landlord, however, measures price differently. He receives a flow of rental revenue in return for providing a bundle of factor inputs. The amount of revenue he receives depends not only on contract rent, but on vacancy rates and collection losses. His unit of operation is the structure, which may contain more than one housing unit. In the event of vacancies or delayed rent payments, he can make only minor adjustments in his inputs, even for a single-unit structure; for a multiple dwelling, he is even more tightly constrained. To him, inputs are commensurable in terms of the prices he must pay for them.

We argue then that the landlord's supply decisions are motivated not by contract rent but by expected net rental revenue, allowing for vacancy and collection losses; and that supply decisions are decisions to increase or decrease factor inputs, taking into account their prices. Presumably, the landlord believes that a judiciously chosen mixture of added inputs will enhance the marketability of his property, leading to an increase in net rental revenue, either through higher occupancy rates or higher rents, or both. His calculation at the margin is a comparison of the expected increase in net rental revenue with the expected increase in total factor cost.

If these are the terms in which supply decisions are made, it seems to us that these are the appropriate measuring sticks for supply responsiveness. Our proposed data-gathering plan and analysis scheme follow this principle, except that we must settle for after-the-fact

*Note, however, that vacant units in a housing market are a floating benefit to tenants, providing accessible alternatives to their present quarters, alternatives to be used in the event of dissatisfaction with their housing, disagreements with their landlords, changes in income or family composition, etc. Over the long run, moreover, the tenants pay for this benefit: The total housing inventory, including vacancies, is supported by the revenues from occupied units.
observations of his revenue and his inputs, as distinguished from his ex ante expectations.*

The scheme summarized earlier for measuring changes in the quantity of housing services is, as we have made clear, really a scheme for measuring the quantity of factors used to produce these services. For vacant units, some factor inputs are discontinued; but unless an entire structure is vacant, the owner must continue nearly all of his outlays because of their indivisibility. Our measurement scheme would capture any reduction in outlays associated with vacancies but would not distinguish inputs to vacant units from inputs to occupied units. If a vacant building was withdrawn from the market—by boarding up, manifest abandonment, condemnation, or demolition—we would cease to count it as part of the housing supply.

For the housing market as a whole, an increase in the vacancy rate would thus imply no more than a small decrease in the quantity of housing services supplied. The decrease in rental revenue would be greater, relative to its base, than the decrease in quantity. It follows, therefore, that a rising vacancy rate, in our accounting scheme, would be accompanied by a decrease in the average unit price of housing services even if rents for occupied units were unchanged. By the same token, a declining vacancy rate would be accompanied by an increase in the average unit price of housing services.

Both the theory of markets and common observation lead us to expect that such changes in vacancy rates would also influence the rents for occupied units. When the vacancy rate rises substantially, landlords are usually compelled to offer rent concessions to hold the tenants they have; when the vacancy rate falls to a low level, they can usually raise rents. Thus, the short-run workings of the market would intensify the direct effects on the average unit price of housing services noted in the preceding paragraph. Over the longer run, however, producers should respond to price changes by altering output in more fundamental ways: withdrawing housing from the market if prices are

---

* Quite possibly, we will find that our analysis is improved by comparing response variables for Period 2 with stimulus variables for Period 1, etc.
too low, adding to the stock if they are profitably high. In the absence of further disturbances, both the price of housing services and the vacancy rate should in time return to "normal" levels.

Thus a market equilibrium—which we expect will be approached within five years after the introduction of the allowance program, barring major exogenous disturbances—is not defined as a circumstance in which all housing units are occupied, or one in which all families are housed, but rather as a level of revenues from occupied housing units such that suppliers are content to neither increase nor decrease the stock of housing units or the level of their current inputs. We would expect the equilibrium vacancy rate to be greater than zero.

Many housing analysts find it useful to view a metropolitan housing market as a set of overlapping submarkets, within each of which special forces affect supply and demand relationships, but always with some spillover into other submarkets. Thus, vacancy rates are seldom uniform across the housing market but vary by neighborhood, rent level, type of structure, etc.

We expect to find such variations within our experimental sites, and we expect the impact of the allowance program also to be uneven. We can enrich our understanding of market dynamics by disaggregating our housing accounts by neighborhood or market sector and relating the observed changes in housing prices and quantities to the initial and subsequent distribution of allowance recipients among these submarkets.

\* \*

Price and Quantity Changes for Owner-Occupied Housing

The analysis plan described in the preceding pages has emphasized supply response in the rental housing market, where tenants and landlords are distinct persons. However, our allowance program also includes assistance to owner-occupants, cases in which the consumers of housing services are also the producers. Here, we explain how our data-gathering plans and methods of analysis deal with this situation.

\* See Sec. VIII for an account of our plans for analyzing the movements of allowance recipients and others within the experimental site.
Our sample of residential structures will include owner-occupied housing units, usually single-family homes but sometimes units in multiple dwellings with resident owners. We propose to treat the latter as rental properties, gathering data on the value of factor inputs for the structure as a whole and on rental revenues from each unit; for the owner-occupied unit, we will accept the owner's estimate of its market rental value. Usually, this estimate should be accurate, since his unit is likely to resemble the rental units in the structure.

Owner-occupied single-family houses are a different matter. Our sample will include both allowance recipients and nonrecipients who are homeowners. How the former respond to housing allowances is indeed an interesting question, but it is more nearly a demand question than a supply question. In the absence of factor-price changes or an increase in real-estate taxes, any increase in housing expenditures by an owner-occupant will be exactly matched by an increase in the flow of housing services as defined by our measurement system. In other words, unlike the case of rental housing, there is no producer's markup entailed in the supply decision of the owner-occupant, and it is this markup which we perceive to be the element of housing price change that is most pertinent to the policy issues of supply response to housing allowances.

Our techniques for measuring changes in factor inputs over time are equally applicable to rental and owner-occupied structures, so for our sample of the latter we will be able to measure changes in the flow of housing services. But for owner-occupied single-family houses, there is no continuous market test of value that corresponds to rental revenue. Rather, we are restricted to sporadic measures, on the occasions when such properties are sold. Then, we are able to identify something corresponding to producer's markup, i.e., capital gain or loss. For properties that change hands after baseline, we can compare the sales price with the baseline appraisal of market value to determine the interim change in the market value of the property. To the extent that this amount differs from the value of recorded capital
improvements less depreciation over the same period, we can conclude that the price of owner-occupied housing services has changed. \* 

We anticipate that about 10 percent of the owner-occupied single-family homes in our sample will change hands annually; over the five-year monitoring period, perhaps 40 percent will have been sold at least once. With the contemplated sample size, \*\* these transaction rates imply somewhere between 100 and 150 observed sales within our sample during the five-year monitoring period--enough to support some general conclusions about price changes, but too few for much disaggregation.

In principle, these data will enable us to construct a price index for owner-occupied homes, using a variation of the Wyngarten method. \*\*\*

For every such property sold during the course of the experiment, we will have data on (1) acquisition price, (2) baseline appraised value, and (3) subsequent sales price. Adjusting between baseline and subsequent sale for capital improvements and depreciation, we can construct price- Relatives for each case, and these in turn readily combine into a general price index for the group, or for its subsets.

With less accuracy, this method can be extended to owner-occupied housing not in our sample of monitored properties that that is sold twice during the term of the experiment, and this may prove to be a desirable special study. Accuracy will be lower outside of our sample because we will lack evidence of capital improvements other than those recorded by alterations permits issued by local authorities; in addition, we will have less evidence on which to sort out "arm's length" transactions from other types of formal conveyances for which recorded prices are misleading indicators of market value.

---

\*To be sure, we could periodically reappraise owner-occupied single-family homes, using the same techniques as for the baseline appraisal; but the major variable in such a reappraisal would be the sales price of the subject property or similar properties, so that going through the motions of reappraisal really adds little more to our knowledge than we have in any case from observations of sales transactions.

\*\* Not yet finally determined.

Transactions in owner-occupied single-family houses can take a variety of forms. Of greatest interest in an allowance-stimulated market are those involving speculative intermediaries—individuals or firms who buy single-family houses, improve them to program standards, and resell them to allowance recipients. Doubtless, our sample of structures will include some cases of this sort, but we will have little difficulty in identifying all such cases through records of the allowance program. Section VII discusses our plans for retrospective analysis of these cases.

ESTIMATING PRICE ELASTICITIES OF SUPPLY

So far in this section, we have explained our plans for measuring the changes in the price and quantity of housing services that occur at our experimental sites, distinguishing as well as we can between changes attributable to the experimental allowance program and changes attributable to background events that are independent of the allowance program. We believe that the techniques we have proposed will enable us to document convincingly the policy-relevant consequences of the experimental housing allowance program at each site, barring other major disturbances of the housing market.

To the extent that experimental findings affect policy decisions concerning a national housing allowance program, we think that this level of reporting will be the most important. However, it does not exhaust the analytical possibilities of our data. Whereas our measures of price and quantity changes tell us directly what happened as a consequence of a specific change in low-income housing demand, they also can be used to estimate what would have happened in response to other untested demand changes.

The analytical machinery needed for such estimates is complicated and relies on data from the Demand Experiment as well as the Supply Experiment. It is discussed in Sec. X of this report, with a mathematical elaboration in Appendix E. For present purposes, we need only note that the critical ingredients from the Demand Experiment are estimates of the price and income elasticities of the demand for housing services, specific to categories of households that are readily identifiable from
commonly available data. From the Supply Experiment, the critical ingredients are estimates of the price elasticity of the supply of housing services, specific to sectors of the housing market that are likewise readily identifiable from commonly available data. In other words, findings from both experiments must be reduced to "portable" parameters, applicable to housing markets that differ in important respects from those in which the data were obtained.

Defining the Price Elasticity of Supply

The formal definition of the price elasticity of supply for an individual producer of a commodity is: The amount by which he would be willing to change his output, given a specified small change in the price at which he expected to be able to sell his product, each change expressed as a fraction of its current base. As a ratio of two ratios, it is easier to grasp in algebraic form than in prose:

\[ e(S,F) = \frac{\Delta S/S}{\Delta F/F}, \]  

where \( e(S,F) \) = the price elasticity of supply;
\( S \) = the quantity of output per unit period of time; and
\( F \) = the expected price per unit of quantity.

Several things should be noted about this definition. First, it describes a hypothetical response to a hypothetical circumstance. Second, it presumes that the only price change taken into account by the producer is a change in the price of output; factor prices are assumed to be unchanged. Furthermore, there is an implicit time horizon entailed in the measure; the producer's willingness to alter his rate of output depends on how he expects the price to change and how long he expects the change to persist. Finally, there is no a priori reason to assume that \( e(S,F) \) is a single-valued function; it is more likely to vary with the values of \( S \) and \( F \), and there is also likely to be some threshold value of \( \Delta F \) below which \( \Delta S \) is zero.

The definition given above was adopted by economists because of its analytical rather than its empirical convenience. All attempts
to measure supply elasticity with which we are familiar fail in one or more respects to meet the rigorous requirements of this definition. This does not make empirical measures valueless; it does mean that if they are used in conjunction with standard market models, due consideration must be given to the ways in which the empirical measure differs from the concept with which it is identified.

Measuring Price Elasticity in the Supply Experiment

As explained earlier in this section, our annual surveys of residential structures will provide data from which we can estimate for each structure separately the annual change in real factor inputs and the annual change in the revenue received by the producer for the resulting housing services. We also show how the revenue change can be decomposed into components reflecting changes in real-estate taxes, changes in the flow of housing services, changes in factor prices, and changes in the producer's markup.

From these data, we can calculate a variety of price elasticities, each with special analytical properties but all based on ex post observation of the outcome of the producer's decision rather than ex ante observation of his assumptions about the future. In each case, the numerator of the measure is the same: the relative change in real factor inputs as measured by our scheme. The denominator varies according to which components of the total price change (relative change in revenue per unit of real factor input) we wish to allow as having influenced the producer's decision.

The most general measure of price elasticity includes all components of price change in its denominator. The producer's response to a change in the market price of his output is here assumed to reflect foreknowledge of or adaptation to the actual changes in real-estate taxes and factor prices that in retrospect affected his costs of production. The "portability" of this parameter is correspondingly limited to market contexts in which the same pattern of tax changes and factor-price changes is anticipated.

Portability can be increased by a series of adjustments to the measured total price change, subtracting out the components that reflect
the changes in real-estate taxes and factor prices. Essentially, the
procedure assumes that the producer discounts an increase in the market
price of output to the extent that it is matched by an increase in fac-
tor prices. It leads to a calculated elasticity that is an estimate of
how he would have responded to a change in the market price of output
in the absence of some or all of the actual factor-price changes.

The reader can see that a long chain of assumptions is entailed
in estimating "portable" supply elasticities, and the final conclusions
will be correspondingly crude. Nonetheless, they will represent a con-
siderable improvement on our present understanding of supply behavior
in the housing market.

**Stratifying Supply Response**

Our panel of residential structures at each site will be stratified
by tenure, size of structure, value per unit, and neighborhood
density (urban, rural), for a total of 16 strata. This system of
stratification was chosen to distinguish sectors of the housing market
that we think are likely to be differently affected by the experimental
housing allowance program.*

The allowance program is designed to increase the housing demands
of low-income families. Given the allowance schedule and terms of pay-
ment and the characteristics of recipients, we expect that their in-
creased housing demands will be more focused in some sectors of the
market than in others. Thus, the demand for modest but certifiable
apartments and single-family houses is likely to increase substantially,
while the demand for luxury apartments or expensive suburban houses is
unlikely to be significantly affected. These differences will be re-
lected in the marketplace by different rates of increase in housing
expenditures by market sector.

Not only will program impacts vary by market sector, but the char-
acteristics of supply response may also vary. For some sectors, output
may increase substantially in response to a small increase in price;

---

*See Corcoran, Poggio, and Repnau, op. cit., WN-8029-HUD. This
document proposes 32 strata, since reduced to 16.
for others, prices may rise sharply with little change in output. In any given sector, the mix of price increases and output increases is likely to change over time.

Using the data on price and quantity changes secured from our stratified sample of residential structures, we propose to estimate the average price elasticity of supply for producers in each sector for alternative periods of time--i.e., for intervals ranging from one to five years from baseline, as our annual cycle of surveys extends the time series. These parameters will be the most portable findings from our study of supply response in our two experimental sites—that is, they will be the information most readily adaptable to analytical integration of our findings with those of the Demand Experiment, and to modeling the results of hypothetical allowance programs in other housing markets.

We should note, however, that the reliability of the estimates will not be uniform across market sectors, for two mutually reinforcing reasons. First, we have chosen to concentrate our survey resources in those sectors of the market that we think are most likely to be affected by the allowance program. Those sectors where only small price changes are likely will be represented in our sample by relatively few cases. At the same time, these are the cases most subject to measurement error. The price elasticity of supply is a ratio of two percentage changes; if either is very small--e.g., if the price change is insignificant--a small measurement error will make a large difference in the value of the ratio.

To put the case more generally, it is not possible to obtain an accurate measure of supply responsiveness in the absence of a substantial stimulus. Consequently, we do not expect to learn much about supply responsiveness in sectors of the market that are not affected by the allowance program.*

*In the first part of this section, we discussed the problem of distinguishing allowance-generated demand changes from exogenous demand changes when we attempt to trace the effects of the allowance program on the housing market at the experimental site. Here, we are concerned with estimating supply response to price changes resulting from any demand stimulus. Thus, there may be increases in the demand
Thus, even our portable parameters will be limited in their usefulness to the analysis of housing markets in which the demand stimulus occurs at the lower end. But since this portion of the market is the locus of policy interest, we can live with this limitation.

For luxury housing, quite unrelated to the allowance program, large enough to provide the data needed for reliable estimates of price elasticity in that sector of the market. But since we are not specifically creating the stimulus, we cannot count on its occurrence.
VII. THE ROLES OF INDIRECT SUPPLIERS AND MARKET INTERMEDIARIES

Investors in residential property rely in varying degrees on external resources to enable them to acquire their properties and to produce and market housing services. In any given case, these resources may include some or all of the following:

1. **Long-term credit.** The real-estate market, more than any other sector of the private economy, depends for its efficient functioning on the ready availability of long-term debt capital for financing the creation, improvement, and transfer of real assets. The principal institutional suppliers of such capital in the residential sphere are savings and loan associations, mutual savings banks, commercial banks, and insurance companies. In addition, the Federal government and several state governments have become important suppliers of funds. In low-income neighborhoods, when loans are not available from these sources, capital is frequently advanced by an individual, often the seller of the property that requires financing.

2. **Insurance.** Property insurance is one foundation of an orderly real-estate market. By enabling the investor to protect himself against large losses, it gives liquidity to real-estate investments and broadens their attractiveness to the investment community. Yet, such insurance often is difficult to obtain at reasonable rates in low-income neighborhoods. Insurers, by necessity, are large corporations.

3. **Brokerage and speculation.** Real-estate brokers are usually called upon for help in buying or selling residential property. In this role, they may be instrumental in implementing informal covenants for residential segregation. In declining neighborhoods or in neighborhoods experiencing racial change, brokers may be unable to find ordinary investors and home buyers for properties that are listed with them for sale. When this situation arises, the broker may either purchase a property on his own account with the intention of reselling, or he may arrange a sale to another short-term investor. This form of speculation provides needed liquidity for the former owner, though usually at substantial cost.
4. **Management.** Most low-income properties are managed by their owners. Some owners, however, contract this function to a professional firm, usually paying a percentage of rental revenue for the service. In either case, the property may be listed with a rental agent who locates and screens potential tenants. His fee is usually paid by the tenant.

5. **Building services, repairs, and improvements.** Owners usually contract out at least some maintenance and operating functions: heavy cleaning, window washing, heating-system maintenance, pest extermination, etc. In the low-income housing market, with which we are primarily concerned, much of this work is done by the owner or his direct employees.

   Major structural repairs or improvements, including electrical, plumbing, or heating-system renovation, are usually contracted out. Homeowners occasionally undertake some of these functions themselves.

---

**POLICY ISSUES AND RESEARCH QUESTIONS**

The availability, cost, and quality of the services provided by these market intermediaries and indirect suppliers powerfully influence the ability of the private market to deliver housing services to low-income families. Their policies and practices directly shape the operating decisions of owners and to some extent determine who the owners will be. One of the objectives of the Supply Experiment, therefore, is to learn whether the stimulus provided by a housing allowance program will substantially alter the attitudes and policies of the firms supplying these resources. It is equally important to learn how the results of the experiment have been shaped by these attitudes and policies.

Questions about the policies of indirect suppliers and market intermediaries have a common feature: Even in an experimental setting, it is extremely difficult to devise robust tests of the changes induced by the allowance program. Some of the individuals and institutions concerned may be reluctant to reveal their practices frankly to an interviewer—all the more when these practices may be either illegal or generally disapproved. Yet a certain amount of systematic data can be
obtained. Combined with informed but informal observation, these data should lead to credible judgments. In the remainder of this section we outline for each of the indirect suppliers and market intermediaries who supply the external resources listed above the major research questions which will be explored, our data-collection plans, and the types of analysis we intend to pursue. Table 7.1 summarizes our plans for data collection related to these analyses.

FINANCIAL INTERMEDIARIES

With the flight of institutional sources of mortgage funds from low-income neighborhoods, real-estate transfers and structural repairs and improvements must be financed by purchase-money mortgages, land installment contracts, loans that are secured by other property, and unsecured personal loans. Since even these noninstitutional and indirect sources may be closed to certain classes of investors, transactions may not be consummated and improvements may not be made for lack of long-term credit. One measure of the efficacy of housing allowances will be the extent to which they are able to restore liquidity to the market by attracting debt capital back into sections of the city that have been shunned by institutional lenders. Equally, a barrier to the success of an allowance program could be the unwillingness of institutions to provide loans for transfers and improvements even where equity investors are prepared to commit capital. For these reasons, the mortgage market will be carefully monitored, both as part of the annual financial survey of owners and by direct interviews with lenders, and where necessary, by analysis of public records. Although an early change in lending policies is not anticipated, observable shifts should occur by the end of the fifth year if they are to occur at all.

In the financial survey, owners will be asked about the characteristics of any loans obtained during the year, as well as about any attempted sales or improvements which were thwarted by unavailability of financing. Where financial data about properties in the sample cannot be obtained from owners, public mortgage records will be examined.

All institutional lenders at the two sites will be interviewed at the beginning of the experiment and annually thereafter. A semi-structured questionnaire will be used. Lenders will be queried concerning the financing they are willing to make available to different types
Table 7.1

SOURCES AND TYPES OF DATA TO BE USED FOR THE ANALYSIS OF INDIRECT SUPPLIERS AND MARKET INTERMEDIARIES

**FINANCIAL INTERMEDIARIES**

1. Annual Financial Survey of Landlords and Homeowners
   a. Characteristics of mortgage loans on property at beginning of experiment
   b. Characteristics of new mortgage loans obtained during the experiment
   c. Perceived difficulties in obtaining mortgage loans for improvements or sale
   d. Perceived difficulties in making payments

2. Public Records
   Mortgage data on properties for which incomplete data are obtained from owners, if the missing data are deemed essential to the analysis

3. Surveys of Institutional Mortgage Lenders
   a. Number of residential mortgage loans outstanding in various parts of the SMSA, by type of property and borrower
   b. Number of residential loans that are delinquent or in default in various parts of the SMSA, by type of property and borrower
   c. Number of residential foreclosures during the previous year in various parts of the SMSA, by type of property and borrower
   d. Number and characteristics of residential mortgage loans made during the previous year in various parts of the SMSA, by type of property and borrower
   e. Official lending policy toward various parts of the SMSA, various types of borrowers, and various types of residential property
   f. Perceived circumstances under which loans with specified characteristics would be made in various parts of the SMSA
   g. Attitude toward specific low-income neighborhoods
   h. Perceived circumstances under which participation in various Federal mortgage insurance programs might be possible
   i. Suggestions for lending programs to complement allowance program

4. Informal Monitoring

**INSURANCE COMPANIES**

1. Annual Survey of a Sample of Companies
   a. Premiums charged for various types of policies in various parts of the SMSA
Table 7.1 (continued)

b. Number of policies actually written in various parts of the SMSA during the previous year
c. Aggregate dollar value of claims paid in various parts of the SMSA during the previous year
d. Attitude toward specific low-income neighborhoods
e. Characteristics of pooled-risk funds, if any such funds exist

2. Interviews with State Insurance Commissioner
   a. Verification of information obtained from insurance companies
   b. Contemplated or existing state programs for high-risk neighborhoods

3. Annual Financial Survey of Landlords and Homeowners
   a. Cost of insurance
   b. Inability to obtain insurance
   c. Cancellation of insurance

REAL-ESTATE BROKERS AND SPECULATORS

1. Administrative Records of Allowance Program
   a. Patterns of residential redistribution of allowance recipients as clues to residential segregation
   b. Reports from allowance recipients of discriminatory practices

2. Administrative Records of FHA Office
   a. Condition of structure prior to sale to allowance recipient and amount of improvements required by FHA
   b. Reports of subsequently discovered structural defects or misrepresentations

3. Informal Monitoring

MANAGEMENT FIRMS AND RENTAL AGENTS

1. Annual Survey of Landlords
   a. Use of services of management firms and rental agents
   b. Tenant-selection policies

2. Informal Monitoring

MAINTENANCE AND REMODELING CONTRACTORS AND TRADESMEN

1. Annual Financial Survey of Landlords and Homeowners
   a. Prices of factor inputs
   b. Opinions of owners as to quality of services supplied

2. Informal Monitoring
   a. Opinions of contractors and others concerning availability of skilled tradesmen, productivity of workers, and quality of work
   b. Opinions of building inspectors as to quality of completed work
of borrowers in various parts of the city. The extent to which these policies are determined by the rules of regulatory agencies will be explored. Information on delinquencies, foreclosures, and voluntary surrenders will also be obtained. Both owners and lenders will be asked about any dealings they may have had with the FHA in connection with the allowance program and whether the FHA created any problems for them.

Although the data on financial intermediaries will not be subjected to rigorous mathematical analysis, it should be possible with the information that will be gathered on sources of financing, types of loans, applications refused, interest rates, amortization periods, etc., to obtain a clear picture of the changing mortgage finance situation in the lower reaches of the market over the life of the experiment.

**INSURANCE COMPANIES**

The attractiveness of residential real estate as an investment depends in large part on its mortgageability, which in turn depends very much on its insurability. Even for the few equity investors who do not rely on mortgage capital to finance their acquisitions, ability to obtain insurance is an important prerequisite to any purchase decision. Thus, unavailability of insurance is certain to contribute to declining market values. It may lead as well to deliberate disinvestment on the part of existing owners who see the market values of their assets eroding and who do not wish to maintain a long-term investment position in unprotected properties.

It is well documented that owners of residential property in low-income neighborhoods are often unable to obtain insurance coverage. Even with assigned-risk pools, insurance in the older areas of some cities cannot be obtained at rates which owners regard as reasonable, and many owners are unprotected. Increased revenues due to housing allowances will partially compensate for the high premiums, thus somewhat alleviating financial pressures on the owner. Whether allowances can also create an environment in which risks, hence insurance premiums, are reduced is a relevant research question. It may, however, be a partially unanswerable question, since insurance reforms, as well as various social programs which could affect underlying risks, are already
under way and will very likely be proceeding independently but alongside the experiment.

Indications of both the initial seriousness of and changes in the insurance situation will be sought from three sources: (a) the annual financial survey of landlords, (b) the state insurance commissioners, and (c) a sample of companies writing policies at the sites. From the landlords we will learn whether the cost of insuring their buildings has moved upward or downward during the year, and also whether any difficulties have been encountered in obtaining insurance. From the insurance commissioners and the insurance companies, we will try to learn what the actual losses in various parts of the metropolitan area have been. In addition, the views of the commissioners and the companies will be sought concerning trends in losses following the introduction of housing allowances. Their judgments and explanations will help us assess whether the allowance program has had any effect on loss experience. Except for the data on losses, all of the information supplied by the commissioners and the companies will be obtained through unstructured interviews. The general reasoning underlying this approach, as it relates to both insurance companies and other market intermediaries and indirect suppliers, is outlined at the end of this section.

REAL-ESTATE BROKERS AND SPECULATORS

Two benefits which some persons hope will accrue from an allowance program are: (a) the dispersion of low-income families into better neighborhoods, and (b) a transition for many of these families from rental tenure to homeownership. These hopes are matched by concern that dispersion may be thwarted by discrimination against allowance recipients, especially those who are members of minority groups; and also that homeownership may be thwarted by exploitation of allowance recipients, as it has been in many cities where low-income households purchased homes with the aid of Sec. 235 subsidies. From the standpoint of the experiment it is important to determine the extent to which the residential choices of recipients are constrained by discrimination on the part of investor-owners or their agents, and also whether exploitation of the low-income home buyer by speculators is likely to represent a major threat to a full-scale allowance program.
Discrimination Against Allowance Recipients

Allowance recipients could be discriminated against in the real-estate market either because they belong to ethnic minorities,* because of their family characteristics, or simply because they are allowance recipients. Discrimination would be indicated by refusal to sell or rent housing to allowance recipients who were able and willing to pay the price at which it was offered to others. In today's legal and political climate, the refusal is unlikely to be overt; rather it would consist of evasions, deceptions, and withholding of information.

Real-estate brokers in many communities are known to play an important role in "managing" housing segregation; by informal agreement, some neighborhoods are declared out-of-bounds for some classes of home buyers. We see no reason to expect that the allowance program, per se, will alter these informal restrictive practices, but it may place additional pressure on them by increasing the financial ability of low-income ethnic minorities to seek homes in neighborhoods from which they are systematically excluded. It is also possible that community groups will seize the opportunity to establish a fair-housing organization or invigorate an existing one.

In our judgment, the number of minority-group recipients—both buyers and renters—who will try to find accommodations in all-white neighborhoods is almost certain to be insignificant even if the allowances which they receive are quite generous. Several studies suggest that the vast majority of low-income blacks prefer to live in predominantly black neighborhoods, and the same is probably true of other low-income minorities as well. Moreover, few families enjoy the role of housing pioneer, and the role is usually played by those who are well up on the socioeconomic ladder. It should be expected, therefore, that only a small number of minority-group recipients will search for homes in white areas that lie well beyond the edge of existing ghettos.

* Only one of our two experimental sites will contain a substantial ethnic (black) minority; this is a deliberate choice, to test how the results of the allowance program will differ between ethnically homogeneous and ethnically disparate communities.
As noted in Sec. VIII, we propose to track and map all changes of residence by allowance recipients. This information, combined with the expected feedback from the recipient counseling program, seems to us to promise insights into both the pattern of residential choices by recipients and the role of discrimination in constraining that pattern. If evidence emerges of discrimination enforced by market intermediaries, the problem and the agents involved can be investigated more systematically. We do not, however, see much value in preplanning a particular style of analysis.

Exploitation of Home Buyers

The possibility exists that a house may be sold to an allowance recipient at a price which is inflated relative to nearby values or to the quality and condition of the structure. With respect to the experiment, two questions must be addressed. First, is this situation likely to occur frequently? Second, can it be adequately monitored by the proposed measurement procedures?

The lessons learned from recent Sec. 235 scandals make it extremely unlikely that excessive markups would escape the attention of the local FHA office, which will administer such loans for the experimental program. Some "excess" profits are likely despite FHA appraisals, since the measurement of property values is imprecise.

Analytically, the profiteering seller is no different from the landlord who raises his rents by amounts that are out of proportion to improvements that he has made in the property. The difference between the two situations lies only in the fact that the landlord's action may be easier to detect, if he is cooperating in providing data for the experiment. However, since owners who sell their properties to allowance recipients must dispose of these properties under an FHA program, it should be easy to obtain data on building condition and on improvements that were made prior to sale. The existence of structural problems that were not apparent to the FHA appraiser can be ascertained by a program of follow-up interviews by the resident observer. Trends in the number and severity of these problems will be analyzed as the experiment proceeds.

The discussion above suggests that a program of housing allowances may engender a certain amount of speculative activity that could thwart
the goals of the program. While this is not improbable, the opposite result should also be anticipated. The role of speculators may become less important as confidence in the future of low-income neighborhoods among potential and existing investors, homeowners, and mortgage lenders grows. If this indeed proves to be the case, the configuration of owners should change over the life of the experiment, as should the nature and volume of transactions. These possibilities will be explored in the annual survey of owners.

MANAGEMENT FIRMS AND RENTAL AGENTS

During the course of the experiment it is possible that the extent to which owners make use of professional managers and rental agents may change. It is also possible that the quality of the firms which supply these services may change or that the quality of the services themselves may change even though new firms do not enter the field in significant numbers. Although we are uncertain as to what sorts of shifts to expect, our annual landlord financial surveys will include questions about such services and thus enable us to detect any significant trends that may be attributable to the allowance program.

Earlier, we discussed the role of real-estate brokers in enforcing residential segregation in the homeownership market. There is a parallel in the rental market, where landlords may accept or refuse tenants on grounds other than ability to pay and genuine evidence of their qualities as tenants. Especially in multiple dwellings, such policies may be implemented by a management firm or rental agent. Our survey of landlords and their agents includes a series of questions on tenant-selection policies, the answers to which can be compared with the characteristics of tenants, directly observed in the course of our household interviews. We should emphasize, however, that we do not expect rental agents to formulate tenant-selection policies; rather, we suppose that they will implement the owner's policies.

MAINTENANCE AND REMODELING CONTRACTORS AND TRADESMEN

Since the experimental allowance program will pay allowances only to those whose housing meets specified standards of quality, the
program may create a sharp increase in demand, at least temporarily, for the services of individuals and firms engaged in maintenance, repair, and rehabilitation. This, in turn, could result in a rise in the price or deterioration in the quality of the services provided. If the latter were to occur, measured "r" in the supply-response formula for investors and owner-occupants would contain a hidden "p" component reflecting the behavior of the suppliers with whom they deal. Elsewhere in this report, we have outlined a method of measuring changes in the prices of factor inputs.* Since the method will not detect shifts in the quality of services, but only their prices, we propose that major changes in the performance levels of suppliers be ascertained as part of the annual landlord and owner-occupant financial surveys. In addition, the informal monitoring described at the end of this section should enable us to discover whether slipshod performance has become a significant problem for the suppliers themselves.

Although our design has anticipated the possibility of price and quality effects in the maintenance, repair, and rehabilitation sectors, it may be useful to explain at this point why such effects are expected to be small. Initially, the allowance program is almost certainly not going to persuade owners to make large investments in their structures. Accustomed to a market where investment horizons are only about three or four years, owners who would have to make large investments in their structures in order to participate in the program will conclude that the annualized cost of improvements is greater than the increase in rents that they could anticipate. So at the beginning of the experiment, we expect rehabilitation outlays to be quite modest, probably averaging no more than $500 to $700 per dwelling unit and rarely exceeding $1,000.**

* See Appendix D.

** Fortunately, expenditures of this general magnitude should be sufficient to upgrade most of the stock to code level. A study by the New York City-Rand Institute in 1969 indicated that the median expenditure required to bring a substandard dwelling into compliance with the New York housing code at that time was $500. (See Lowry, op.-cit., p.4643.) A similar study in Baltimore in the same year by the Institute for Environmental Studies, University of Pennsylvania, found that 60 percent of the substandard inventory could be brought up to code
The probable impact of expenditures of this magnitude can be estimated with the aid of a few additional assumptions. If, at a site of 60,000 households, one-fifth (12,000) of the residents qualify for an allowance; and if four-fifths (9,600) of those who qualify actually sign up for assistance; and if, of those who sign up, one-fourth (2,400) are already adequately housed, one-half are in modestly substandard units, and one-quarter are in units requiring intermediate or extensive treatment; then the maximum demand for additional rehabilitation services would, in the short run, be confined to only 4,800 units or about 8 percent of the stock. If we assume generously that all 4,800 units are upgraded over an 18-month period at an average expenditure of $700 per unit, the total investment for the first year of the program would be on the order of $2,000,000. This figure is equivalent to about 100 units of new construction and roughly 100 man-years of site labor. These are magnitudes which imply little stress on the supply side, unless the allowance program were introduced in the midst of a major building boom. To the extent that shortages did emerge, they would impact primarily on small investors and homeowners, who do not have well-established connections with the building trades. Because they do not have these connections, however, they could be expected to do some of the necessary work themselves, thereby reducing the possibilities of stress even further.*

Such stress on prices and quality as does emerge during the first year or two could possibly be counteracted by the sort of technical assistance that is available in the Sec. 312/115 program. The question of whether to supply such assistance, however, is primarily a program, not a design, issue.

for a cost of less than $1,000 per dwelling. See William Grigsby, et al., Housing and Poverty, Institute for Environmental Studies, University of Pennsylvania, 1971.

*In neighborhoods where the prices of factor inputs are already quite high because of the extra risks of theft and bodily harm, it is not inconceivable that a program of allowances could reduce risks and prices. Such neighborhoods do not exist at the experimental sites, however.
LEARNING FROM INFORMAL OBSERVATION

Statistical analysis of the systematic data described above should go part way toward answering our questions about the responses of indirect suppliers and market intermediaries to a housing allowance program. Such analysis, however, will have a strong tendency to fragment data into its smallest manageable units, good for testing hypotheses but poor as a method of synthesis. Yet a major part of our research problem is to discern coherent, clearly motivated patterns of behavior. For this purpose we think that informal monitoring is an effective tool. It will permit us to piece together a large array of disparate pieces of information gathered as part of the more formal surveys. It is not difficult to find local lenders, landlords, real-estate brokers, and public officials who will talk freely about "what is going on" in the real-estate market. Much of the information thus obtained may be unreliable, consisting of either unwarranted generalizations from a few incidents, biased accounts of personal dealings, or hearsay. But usually there is a germ of truth in even the unreliable accounts. An observer who can tell a hawk from a handsaw can detect these pieces of the truth, rationalize seemingly conflicting points of view, and formulate hypotheses. He can pursue these hypotheses for additional evidence, unconstrained by the structured framework of a systematic survey. His conclusions may not rest on statistical evidence, but they are likely to be vivid in the sense of capturing complex, partly irrational patterns of behavior. If the issues raised by his conclusions are of critical importance, they may be further pursued by well-targeted, limited-purpose survey work or analysis of public records.

In this part of the experiment, therefore, we propose to count what can be easily counted, then rely on our resident observers to guide any further systematic investigations into the behavior of indirect suppliers and market intermediaries. This procedure will lead us to ask new questions throughout the course of the experiment rather than force us to formulate all questions a priori and possibly miss a number of pertinent questions in the process. Given the length and complexity of the experiment, we regard this approach as essential to the success of the overall effort.
VIII. RESIDENTIAL MOBILITY AND NEIGHBORHOOD CHANGE

Each year, about 20 percent of all households in the United States change their places of residence; among renters and among low-income households, the proportions are higher. About two-thirds of all moves are local, to a new address within the same city or county; the remaining third are, in descending order of frequency, intercounty, interstate, or interregional. Here, we are concerned primarily with local moves and how their frequency and spatial patterns may be affected by a housing allowance program.

POLICY ISSUES AND RESEARCH QUESTIONS

Local population movements due to low-income housing assistance programs have become a matter of increasing policy concern. The largest such program, public housing, was originally intended to clear existing slums, rehousing the former residents at the same sites. For a variety of reasons—the long redevelopment cycle, deliberate reduction in residential density, and tenant selection policies that excluded many slum residents—this was seldom the result. Instead, most of the former population of a redeveloped site usually dispersed into nearby neighborhoods where housing was cheap, reestablishing slum conditions not very different from those of their former location.

Since World War II, Federal and local policymakers have experimented with a variety of alternatives designed to escape this dilemma: instead of demolishing slum housing, rehabilitating it without displacing its low-income tenants; building public-housing projects in middle-income neighborhoods to avoid the wholesale displacement of a slum population; building small-scale projects in scattered sites to minimize social impact on the "host" neighborhood; dispersing low-income families into subsidized private rental housing, often selected units within buildings the bulk of whose tenants were unsubsidized; and providing heavy mortgage subsidies to enable poor families to become owners of homes scattered through middle-class neighborhoods.
In some respects, the housing allowance concept is the logical culmination of this line of social experimentation. It entails no forced displacement of slum dwellers and no directed relocation of assisted families. Because the subsidies would be attached to eligible households rather than to particular housing units, recipients of housing allowances would have a wider range of choice as to type, tenure, and location of housing than under any previous program, constrained only by what the private market offers that is within reach of an allowance-augmented budget. But if these choices are to be left to allowance recipients, it becomes important to anticipate the residential redistribution and neighborhood changes that would ensue from a housing allowance program.

In the Supply Experiment, the range of choice permitted by the experimental allowance program designed within the constraints of Sec. 23 and Sec. 235 is only slightly less than would be the case under a "pure" housing allowance scheme. Households may be assisted as renters, as homeowners, or as home buyers; they may shift from one tenure to another and from one residence to another within the boundaries of the experimental site without loss of eligibility. For renters and homeowners, benefits under Sec. 23 will be identical, and the only restriction on housing choice is that the unit must meet minimum standards of quality and size; but for home buyers, conditions of eligibility for mortgage subsidies under Sec. 235 are more stringent and benefits generally greater than those for renters and homeowners under Sec. 23, and this subsidy is not automatically transferable to a different house if the assisted household should later decide to move.

For those enrollees who are dissatisfied with the housing they occupy or with the neighborhoods in which they live at the time of enrollment, the allowance program provides an opportunity to move. If their housing is substandard, the program provides an incentive to move, since allowance benefits are restricted to those living in standard housing; enrollees must either forgo the allowance, persuade their present landlords to make the improvements needed to meet code standards, or move to housing that is already in acceptable condition.

It is thus reasonable to anticipate that the experimental allowance
program will generate pressure on building owners (through their tenants) to make improvements and will also produce changes of residence by enrollees. We expect the amount of movement by enrollees to depend both on the speed with which landlords respond to this new incentive and on the vacancy rates * in standard units, both in the enrollees' neighborhoods and elsewhere in the metropolitan area.

Somewhat more problematical will be the effect of the allowance program on the mobility of nonparticipating households. Some of these households may move because of rent increases traceable to the allowance program; others may move because they object to allowance recipients who appear in their buildings or neighborhoods; others who wish to move for housing reasons may be restricted in their choices by more vigorous competition for standard housing.

There is little question, then, that a housing allowance program could result in rapid spatial redistribution of program participants; they would have the means, the motive, and, presumably, the opportunity to relocate. But whether a housing allowance program would have this result is another matter, about which well-qualified observers disagree.

Some of the disagreement may be traceable to the lack of a clear assumption about the level of assistance provided by an allowance program. While such a program, as we conceive it, does not place a ceiling on the amount that an assisted family may pay for rent or ownership, what is presently known about the income elasticity of housing demand (less than unity) indicates that some form of earmarking would be needed to increase the recipient's housing expenditures by as much as the amount of the allowance. Thus the program's target level of housing expenditure is an upper bound. No one, to our knowledge, has seriously proposed an allowance formula that would enable recipients to afford new

---

*It is easy but erroneous to suppose that the number of vacant standard units sets an upper limit on the number of moves by program participants. It sets an upper limit only on the number of substandard units that can be abandoned by program participants without displacing nonparticipants from standard housing. High turnover rates are found in urban areas with both high and low vacancy rates. Thus, New York City had a rental vacancy rate of 1.2 percent in 1968, but 15 percent of all renters moved during the preceding year, not counting those who left the city.
housing, or even expensive existing housing. At best, the target would be the median rent in the community, and well below the median annual cost of owned homes.

Thus, allowance recipients might be able to afford the costs of perhaps one-third of the community's housing stock. The housing within their reach would be concentrated in the older neighborhoods; by and large, the suburban developments of the 1950s and later would be out of reach for all recipients except those who placed an especially high value on housing, as opposed to other forms of consumption.

If this portion of the stock contained, as we expect, too few available vacant standard units to accommodate all allowance eligibles, there could follow competition between them and the ineligible occupants of such housing. The aim of the housing allowance program is to match supply and demand by inducing improvements in below-standard housing and forestalling the present process of deterioration to which standard units are subject when their tenants are unable to pay the cost of adequate maintenance.

In sum, we do not expect wholesale relocation of program participants from their preenrollment neighborhoods to distant parts of the central city or metropolitan area. Most moves by participating households, we think, will be within their preenrollment neighborhoods or to the fringes of them, in the classic pattern of ghetto expansion.

Nonetheless, it is important to test the a priori reasoning explained above. Any substantial relocation or redistribution of households within the metropolitan area, if it occurred, would be a result the detailed nature of which would be extremely important to understand.

From one standpoint, residential redistribution resulting from an allowance program is a potential side effect of considerable political and social importance; we will want to know in detail what to expect and why it occurs. From another standpoint, residential mobility is part of the process by which the housing market matches supply and demand. What role does it play in the context of a housing allowance program? Can we infer that inducing or encouraging mobility would have a positive effect on the supply response? Our information on the dynamics of the market response to an increase in low-income housing demand
is scant. The pattern of mobility can tell us much about the reaction of both buyers and sellers in this situation.

Additionally, the allowance program is likely to affect the mobility of participants and nonparticipants differently. These differences, too, are important subjects for analysis. Section IX deals with the general question of measuring impacts on nonparticipants (considering the experiment as a whole), but we are concerned with them here as well.

These policy interests require investigation of a number of specific questions, which can be grouped as follows:

The amount of moving. Will the amount of moving, or the frequency of moves, change when the allowance program is implemented? Will we observe a temporary increase in moving, followed by a resumption of the "normal" rate, or will we find the moving rate to be at a permanently higher level? Will participants and nonparticipants be affected alike with respect to frequency?

Spatial aspects of moving. Next to frequency, the spatial pattern of movement is the most significant aspect of increased residential mobility. We will be concerned with how program participants distribute themselves in the metropolitan area over time, and with the geographical origins and destinations of participants and nonparticipants, before as well as after program implementation.

Causes of moving. Who moves, and under what circumstances? Will the allowance program affect the propensities to move of both participants and nonparticipants? What characteristics of the "old" housing or neighborhood and what characteristics of the "new" affect moving decisions most? Will the type of households or the housing variables change as a result of the allowance program? If an eligible household must move to obtain certifiable housing, will it do so, or will it decline the allowance?

Results of moving. Is mobility a significant factor in upgrading housing? Do participating households typically upgrade their housing to certification quality by moving, or by obtaining improvements in the units they occupy? Does tenant turnover decline in buildings to which improvements are made? Do participating households tend to displace
nonparticipants from certified or certifiable units? Will increased moving activity lead households to adopt new procedures for locating available units?

**Sources and Characteristics of Mobility Data**

Our present monitoring plans provide us with two major sources of data that can be used to address these questions: administrative records of the allowance program, and the annual survey of households living in our sample of residential structures. To supplement the latter, follow-up surveys of movers may be needed in years subsequent to baseline.

The enrollment and recertification records of the housing allowance program will contain detailed information concerning the household characteristics of enrollees and their housing, necessary for determining eligibility and allowance payments. Their changes of residence can be continuously tracked for the entire period of enrollment.

The survey of sample structures and their residents is described in Sec. IV. For households included in the baseline sample, we will obtain retrospective data on places of residence and reasons for moving, as well as household characteristics at the time of each move. Our most detailed data on housing and household characteristics will relate, of course, to the respondents' circumstances at the time of the survey.

This sample will include both program participants and nonparticipants, with the latter predominating. While participants, whether in this sample or not, can be tracked by administrative records, a special effort would have to be made to track nonparticipants. Our annual cycle of household interviews will encompass only the original panel of housing units, so that we are sure of reinterviewing only households that do not move. For those that move, we will know only the date of departure, unless they happen to move into another monitored housing unit. Households that were not included in the baseline survey but later move into a monitored structure will be interviewed by the next annual survey, and their housing and mobility experiences can then be captured.

Some of the analyses described below will be incomplete unless nonparticipants interviewed at baseline are followed when they move. However,
we do not think it is essential to commit ourselves firmly to tracking
all of them to their new residences, since the decision has no implica-
tions for planning the baseline surveys. Experience in other surveys
indicates that such follow-up operations are time-consuming and expen-
sive; we think the decision should be deferred.

Mobility Patterns for Program Participants

As noted above, the administrative procedures of enrollment and
disbursement and housing inspection will enable us to track the resi-
dential locations of all enrollees as long as they continue to partici-
pate in the program, providing a complete residential history extend-
ing from the date of enrollment to the end of the five-year monitor-
ing period or to the enrollee's separation from the program, whichever
comes first. The analytical task is to discern and document patterns
in these linked records. We propose to search for several kinds of
patterns:

Spatial redistribution of program participants. We will compile
an annual inventory of the residential locations of all program par-
ticipants by small areas (e.g., census tracts). Differencing these
annual inventories will tell us where in the metropolitan area the
allowance-receiving population is growing and where it is decreasing.

Origin/destination of moves. We propose to construct annually a
matrix of moves by small-area origin and destination. This matrix
will display the flows whose net results are recorded in the analysis
described in the preceding paragraph. Examination of the large flows
will lead to specific hypotheses that can be statistically tested.
Since these hypotheses will concern both movers and nonmovers, the dis-
cussion that follows applies to both, i.e., a nonmover is one whose
origin and destination are identical.

Characteristics of origin and destination neighborhoods. One
hypothesis to be tested is that the rate of flow depends on neighbor-
hood characteristics at origin and destination. A basic delineation
of neighborhood characteristics will come from our neighborhood survey:
land-use patterns, characteristics of residential buildings, availability
of services and facilities, characteristics of residents, and "social indicators" of the quality of life.

**Characteristics of origin and destination housing.** Our data file will show, for each mover who is an allowance recipient, the general characteristics of the structure and the housing unit he occupies before and after each move, tenure, and rent. Careful application of multivariate analytical techniques should enable us to distinguish housing factors from neighborhood factors in explaining patterns of movement. This analysis will be integrated with a substantially similar analysis of the household-survey data, which covers nonrecipients. The analysis and underlying regression model are discussed at greater length below.

**Characteristics of movers.** We would expect some subgroups within the population of allowance recipients to have a greater propensity to move than others; subgroup moves will also differ in origin and destination characteristics. Again, multivariate analysis should enable us to relate mover characteristics to both neighborhood and housing characteristics, and again, the analysis will parallel, and be integrated with, the analysis of the household-survey data.

**EFFECTS OF THE ALLOWANCE PROGRAM ON MOBILITY**

In the preceding subsection we described a group of analyses designed to reveal the pattern of movement by program participants and their consequent redistribution within the metropolitan area. This information is directly responsive to concerns that have been voiced about residential redistribution associated with a housing allowance program—either that program participants (especially ethnic minorities) will move away from neighborhoods in which they are now concentrated, or that they will not do so.

However, these descriptive analyses fall short of a policy-relevant explanation of the events observed. They do not enable us to answer, except intuitively, the question of whether the same or a different pattern of movement would have occurred in the absence of an allowance program. We propose to seek more objective answers to this question.
through a four-way comparison of moving behavior: program participants versus nonparticipants, before and after the commencement of the allowance program.

1. Preallowance mobility patterns. What characteristics of households, housing, or neighborhoods influence the frequency of movement and the origin/destination of moves before the commencement of the allowance program? Classifying households according to whether they later participated in the program, were preallowance mobility patterns different for participants and nonparticipants? What characteristics seem to account for the differences?

2. Postallowance mobility patterns. What characteristics of households, housing, or neighborhoods influence the frequency of movement and the origin/destination of moves after the allowance program commences? Classifying households according to whether they are participants or nonparticipants, how do mobility patterns differ? What characteristics other than participation status seem to account for the differences?

3. Changes in participant mobility patterns. Comparing the preallowance and postallowance moving behavior of those who enroll in the allowance program, do mobility patterns change in terms of frequency or origin/destination of moves? Can the observed changes in mobility be accounted for by factors operative prior to the allowance program—for instance, by changes in household composition or nonallowance income?

4. Changes in nonparticipant mobility patterns. Comparing the preallowance and postallowance moving behavior of those not enrolled in the allowance program, do mobility patterns change in terms of frequency or origin/destination? Can the observed changes be accounted for by factors operative prior to the allowance program?

These comparisons can be made at different levels of statistical sophistication, but an attractive approach is an adaptation of the demographer's technique of standardization based on regression analysis.
Thus, for frequency of movement, this would entail fitting equations separately for each of the four strata of households (preallowance participants, preallowance nonparticipants, postallowance participants, postallowance nonparticipants); in each equation, the probability of moving within a specified period of time would be expressed as a function of selected household characteristics (such as age, sex, and race of head, marital status, size of household, income), selected housing characteristics (such as rooms per person, rent/income ratio), and selected neighborhood characteristics (distance to place of work, ratio of respondent's rent to neighborhood median, congruence of respondent's characteristics with those of the neighborhood's population).

By exchanging coefficients of the fitted regressions among the four strata, it is possible to decompose the observed differences in frequency of movement into differences in the characteristics of the population represented in each stratum and differences associated with the stratifying variable, i.e., relationship to the allowance program.

Short of a classical experiment with matched control and treatment groups, this technique comes as close as possible to isolating the effects of the allowance program on both participants and nonparticipants.

A similar approach is applicable to origin/destination of move, though additional reservations are in order here. To use such a model, the relationship of origin and destination must be expressed as one continuous variable (e.g., distance between origin and destination, ratio of (or difference between) a quantitative characteristic of the origin to the same characteristic of the destination).

---

*That is, data for the preallowance period on households that later enrolled in the allowance program.

**The reader will note that the examples given of housing and neighborhood characteristics are expressed relative to some characteristic of the respondent's household. While nonrelational variables might also be used, this form seems to us to have special promise, as a way of indicating the degree to which the household is satisfactorily integrated with its residential environment.
An alternative technique that is perhaps more appropriate to this problem is to classify origins and destinations into a manageably small number of categories of research or policy interest (for neighborhoods, perhaps by ethnic mix or median value of housing units) and represent the reported moves by respondents in each stratum as transition matrices linking these origin and destination vectors. Exchanging transition matrices among the four strata, we can decompose the differences in the destinations of each group into differences in their origins and differences in patterns of movement for each stratum from given origins.

These analyses would be easiest to perform if nonparticipants as well as participants were tracked when they moved from monitored structures. A less sturdy but practicable approach could be developed even without this feature, by retrospective questioning of nonparticipants encountered in the monitored structures for the first time in one of the postenrollment surveys.

MOBILITY AND HOUSING IMPROVEMENT

Households move for many reasons, only one of which is to improve their housing. Those eligible for housing allowances, however, have a particular incentive to move for this reason. Below, we describe several topical analyses that will help us to understand the role of mobility in securing housing improvements.

Housing Improvements for Movers and Nonmovers

When the allowance program opens for enrollment, some eligible households will be living in housing that is certifiable under program standards. In order to qualify for allowance payments, they will need only to enroll and have their housing inspected and certified.

Most eligible households, however, will be found in noncertifiable housing. To qualify for allowance payments, they will have to either persuade their present landlords to upgrade the property to program standards, or move to another unit that is certifiable. Which course they follow is a matter of considerable policy interest and
is indicative of landlord responsiveness to allowance-created demand for housing improvement.

Data bearing on this issue are available both from administrative records of the allowance program and from the sample survey of households in monitored structures. From the former source, we can obtain a list of applicants to the allowance program who are (a) declared eligible and (b) told that their present housing is unsatisfactory. Following these households over time, we can tabulate the proportions who (a) move into certifiable housing, (b) subsequently obtain certification of their original housing, and (c) do neither, thus losing their allowance entitlement. Within the first two groups, we can further tabulate cases by elapsed time between enrollment and certification. These data form a basis for reasonably strong inferences about the effectiveness for allowance recipients of each course and the frustrations they may encounter.

We can also expect the size of the available allowance to affect the program applicant's incentive and the leverage he will have in dealing with his current landlord or with landlords of buildings to which he may consider moving. Whether or not larger allowances will be associated with an increased tendency to move is problematic but is a question which we wish to examine. Accordingly, we will also tabulate the proportions of eligible applicants in the three groups above—those who move into certifiable housing, those who get their original housing certified, and the others—by the amount of the allowance they receive or for which they are eligible. This can be done at semiannual intervals from the enrollment and recertification records.

One weakness of these data is that they exclude eligible households who never apply for the allowance program. There may be many reasons for not applying, but one is that the household concludes from its understanding of program rules that its present housing is uncertifiable and the household is unwilling to move. From records of the baseline survey, we expect to be able to classify households as eligible or ineligible for enrollment, and their housing as certifiable or uncertifiable—not with the rigor required for program
administration, but accurately enough for research purposes. We propose a follow-up by the resident observer of a sample of eligible nonapplicants to ascertain why these households failed to apply. Findings from this follow-up study may modify conclusions reached from the analysis of program records described above.

Housing Improvements and Tenant Turnover. Another perspective on these issues is provided by tracking the histories of individual structures with respect to housing improvements and relating these events to tenant turnover and vacancy rates. Thus, we can determine whether a landlord strategy of housing improvement in an allowance-stimulated market is rewarded by less turnover and higher occupancy rates. Possibly, the data from the landlord financial survey will be precise enough on a building basis to test whether there is a systematic relationship between the owner's markup rate on factor costs, as reflected in his rent schedule, and the actual profitability of his operation, taking into account rent losses from turnover and vacancies.

Housing Succession: Participants and Nonparticipants. As we have noted, the allowance program will put participants on a competitive footing with nonparticipants for housing previously beyond the means of the former group. We will be able to determine who succeeds whom in the occupancy of specific units for our sample panel of structures. Sorting these findings by structure characteristics and rent levels should tell us a good deal about where in the spectrum of housing types and costs to anticipate the greatest competitive pressure from allowance recipients in a national program.

Triggering Events. Many of the moves by those enrolled in the housing allowance program will manifestly be triggered by the need to find certifiable housing so as to become eligible for allowance payments. However, not all moves, whether by program participants or others, are solely motivated by a desire for better housing or even better neighborhoods. And whatever a household's general preferences, a decision to move is likely to reflect some recent change in its circumstances that causes the members of the household to reevaluate alternatives.
Frequently, moves will reflect changes in household size, changes in job location, rent increases, or quarrels with the landlord. In our household surveys, we will record the reasons supplied for moving, although experience indicates that it is not easy to get an unequivocal explanation of the reason for a move from the respondent. We propose, therefore, to analyze the timing of moves relative to recorded events in the respondent's history (such as a change of jobs or of income or household size) and to compare housing characteristics before and after the move. Such an analysis, we think, will clarify the relationship of housing satisfaction and dissatisfaction to family life and will cast at least some light on a household's success in remedying its housing problems by moving.

HOUSING SEARCH PROCEDURES

The experimental housing allowance program is designed to enable low-income families to afford better housing than they generally occupy, but it relies on their individual efforts in the marketplace to obtain certifiable units, either by moving or by inducing their present landlords to provide the needed improvements. The portability of their allowances is essential to their bargaining power in the marketplace; but this feature could be nullified by lack of initiative, skill, or information in exploring alternatives to their present quarters.

Sociologists have often commented on the limited horizons of urban dwellers, particularly the poor. We suspect that lack of information about housing opportunities outside their immediate neighborhoods, combined with timidity about exposing this ignorance, is a substantial factor in the cohesiveness and persistence of segregated low-income neighborhoods, at least third in importance behind racial discrimination and lack of means.

Participants in the experimental housing allowance program will be offered counseling and guidance in how to look for housing, in how to judge its quality and appropriateness to their family circumstances, and in their rights and obligations as tenants or home buyers. These features of the program could prove to be as important as the allowance in helping enrollees to achieve their objectives. It is not intended,
however, that the counselor act as real-estate agent on behalf of the enrollee; given good advice, the enrollee will still have to conduct his own search, make his own choice, and negotiate his own terms with the landlord.

Our program of household surveys offers us the opportunity to evaluate the effectiveness of the counseling program in several respects; here, we focus on its contribution to skills and initiatives in searching the market for housing alternatives. At baseline, each respondent will be asked to describe the methods he used to find his present housing and the duration of search. Similar questions will be asked on subsequent annual surveys. Thus, we will be able to associate search methods with household characteristics and learn how the patterns change over time.

The formal method for analyzing these data parallels in many respects the technique proposed for determining the effects of the allowance program on mobility. Stratifying baseline respondents into those who later become program participants and those who do not, and similarly stratifying respondents to postallowance surveys into participants and nonparticipants, we can construct four strata for parallel analysis. Within each stratum, we can statistically associate search techniques not only with household characteristics, but also with the respondent's satisfaction with the housing he finds. Inter-stratum comparisons will enable us to see how these relationships change for program participants before and after enrollment and counseling; and for nonparticipants before and after the housing market is perturbed by the allowance program.

The latter point conceivably could be important. If the allowance program creates excess demand for particular kinds of housing, or for housing in general, search procedures that were effective in a looser market may fail to serve as well. How quickly our respondents master more appropriate techniques, and what types of respondents are most adaptable, could significantly affect the way in which housing is redistributed in an allowance-stimulated market.
IX. EFFECTS OF HOUSING ALLOWANCES ON NONPARTICIPANTS

The direct and indirect effects of housing allowances may extend considerably beyond participating families and those who supply these families with shelter. In every neighborhood in which participants reside at the beginning of the experiment, there will be a number of nonparticipants. Even within a single residential block, it is unlikely that the incidence of allowance-eligible households will ever rise above two-thirds of the total; and for larger neighborhoods, one-half seems a likely limit. Moreover, as some of the participants disperse to new neighborhoods, the spatial intermingling of the participants and nonparticipants will become, if anything, even more pronounced. For a fairly large portion of the total market, they will compete for the same housing and will mutually shape the same environment.

POLICY ISSUES AND RESEARCH QUESTIONS

Nonparticipating families may thus be affected by an allowance program in both obvious and subtle ways. Some may experience rent increases as a result of added housing demand on the part of participating households. Others may find their neighborhoods being "invaded" by a socioeconomic or racial group that they would like to avoid. Others may observe improvements in their social and physical environments as the additional income of participating families is translated into home repairs, increased owner-occupancy, better landlord-tenant relations, less involuntary mobility, and more permanent interest in the neighborhood. Finally, at least a few nonparticipants may watch their neighborhoods deteriorate as participant families move on to better areas and are not replaced by other households.

The political acceptability of a housing allowance program will depend as much on its actual and perceived effects on nonparticipants as on its benefits to participants. An important goal of the experiment, therefore, is to measure the various ways in which allowances alter the housing choices and neighborhood environments of nonparticipants; another objective is to ascertain their reactions to the program.
Since our general research concern with nonparticipating households is the same as that for participating families and their housing, most of the conceptual and measurement issues that were discussed in Secs. VI and VIII apply here. This section focuses on the ways in which nonparticipants will receive special treatment in our research and analysis.

The discussion is divided into two parts. First, we review the ways in which the allowance program may affect the housing choices and neighborhood environments of nonparticipants, and how those effects can be measured. Second, we consider how nonparticipants may perceive the allowance program's effects, and how changes in their attitudes can be measured.

Housing Choices and Neighborhood Environments

We foresee three ways in which the lives of nonparticipants may be significantly affected by the experimental housing allowance program: (1) through changes in the cost or availability of suitable housing, (2) through changes in the physical characteristics or social milieu of the neighborhoods in which nonparticipants live, and (3) through residential relocation in response to changed housing or neighborhood conditions. Because these changes are interactive, we discuss them together below.

Availability and Cost of Housing

A frequently expressed reservation about the wisdom of undertaking a national program of housing allowances is the potentially adverse effect of such a program on the housing consumption of nonparticipants, especially those whose incomes are not far above the upper limits of allowance eligibility. Those who voice this concern usually point out that large-scale disbursement of such allowances to low-income families would substantially increase the demand for better housing without guaranteeing any increase in its supply. The likely consequence, they argue, is inflation in housing rents and prices due to excess demand. Nonparticipants would have to either reduce their housing consumption or reduce other expenditures to cover the increase in their housing costs.
If the allowances are generous, participants may even be able to out-bid nonparticipants for the limited supply of better housing units. Not only does this seem an inequitable redistribution of housing resources, it entails little net improvement in communitywide housing conditions.

This scenario assumes a very inelastic supply function for housing services in the sector of the housing market serving families of low-to-moderate incomes. Its inarticulated premise seems to be that a significant increase in the supply of housing services occurs only through new construction. Even with their augmented resources, program participants will seldom be able to afford new housing; therefore, the allowance program will not stimulate an increase in the supply of housing services to match the increased demand. *(1)*

What the argument overlooks or dismisses is the possibility of preventive maintenance and capital improvements in the existing inventory. Such improvements were common during the 1950s, a decade of dramatic increase in real income and housing demand. Nationally, the Bureau of the Census estimates that some 5 million housing units out of the 17 million that were substandard in 1950 had been upgraded to standard condition by 1959. **(2)** Although the Bureau has not made comparable national estimates for the decade 1960-1969 and did not make comparable appraisals of housing quality in the 1970 Census of Housing, indirect evidence and special studies indicate that the pace of housing deterioration increased during the decade, particularly in large central cities. ***

---

**(2)** U.S. Census of Housing, 1960, Vol. IV, Components of Inventory and Change, HC(4), Part IA, No. 1. The Bureau estimates the reverse flow of substandard to substandard, at 1.7 million units, including substandard units created by conversion and related means. In addition, 1.2 million units constructed during the decade were substandard in 1959.

***

Our point is that there is substantial room for housing improvement without resorting to new construction, through upgrading the existing inventory and--equally important--by applying a greater maintenance effort to forestall deterioration. Elsewhere, we have argued that housing deterioration is usually attributable to lack of effective demand, i.e., to lack of tenants who are able and willing to pay the full costs of adequate maintenance. * We will not repeat that argument here; suffice it to say that the Housing Assistance Supply Experiment will provide a test of this hypothesis. If it proves correct, allowance recipients will be able to obtain better housing without seriously inconveniencing nonrecipients. Both groups, able to afford decent housing, will be able to get it through normal market channels.

Section VI above describes our plans for measuring the responsiveness of housing suppliers to the experimental allowance program. For each of the monitored residential structures, we have proposed careful measurement of the inputs employed by the owner to produce housing services before and after the allowance program is initiated. At the same time that we measure changes in the flow of housing services, we will measure changes in rents paid by residents. We expect rents to increase as a result of the demand pressure created by the allowance program. The critical question is the extent to which the increase in rents will be accompanied by an increase in the flow of housing services.

Market theory tells us that the impact of the allowance program on the housing of nonrecipients should be reflected in these aggregate changes, because price changes tend to diffuse through the market. If the unit price of housing services rises sharply, nonrecipients will be inconvenienced thereby; if the increased spending by allowance recipients is nearly all reflected in increased services, the program's price effects on nonrecipients will be negligible.

Our analysis plan will provide a clear measure of the annual average change in the price of housing services within the experimental site, but this may not be the whole story. Housing services come in packages, by dwelling units, and consumers differentiate among these

---

*Lowry, ibid., pp. 490-496.
packages in the same way that they differentiate among makes of automobiles. Demand pressures focused on a particular type of housing may cause its price to rise more than the prices of other types, without a corresponding change in factor inputs. The presence in the market of less-favored but cheaper alternatives serves to limit price differences of this type, but it does not eliminate them.

Here, we are interested in the possibility that those who do not receive housing allowances will encounter price increases that are different—greater or less—from those encountered by allowance recipients. The structures in our sample can be divided into subsets, and the housing accounts described in Sec. VI can be compiled separately for each subset. We propose to compare accounts for the subset of structures most of whose occupants are program participants with accounts for subsets most of whose occupants are nonparticipants, simultaneously controlling on the neighborhood incidence of program participants. This procedure should reveal with reasonable accuracy whether the price effects of the experimental allowance program are different for program participants and for various categories of nonparticipants.*

We have argued (in Secs. VI and VIII) that neighborhoods with a high incidence of program participants will be the loci of the highest demand pressures. Absent the perfect market of textbook fame, housing prices in these neighborhoods should rise before prices in the others. We can again turn to the housing accounts to test this hypothesis. One approach is to classify each structure into one of several groups according to the incidence of participants in the neighborhood in which it is located, then compare the average price increases for the several groups. Alternatively, we can use the neighborhood as the unit of observation and regress average price change against the proportion of households that are program participants. Comparing these results for successive years will provide insights into the pace.

* However, we should note that the reliability of our price-and-quantity-change measures decreases as the number of structures in a subset decreases. In particular, disaggregation can lead to aberrant results because of the lumpy effects of chance vacancies.
and completeness with which allowance-created demand pressures are propagated into market sectors in which direct effects (as evidenced by the concentration of recipients) are small.

In both of the analyses described above, various groupings of structures would be followed through time, and changes in the price and quality of housing services yielded by each would be measured by the method described in Sec. VI. Differential effects of these changes on participants and nonparticipants would be estimated on the basis of the changing incidence of each class of household in the structure or its neighborhood.

An alternative approach to measuring these housing effects on nonparticipants is to track individual nonparticipating families, rather than structures, noting the changes over time in their housing consumption and in the prices they pay for housing. For those who remain in the same structure, the two approaches are identical. For those who move from one monitored structure to another, price/quantity relationships for origin and destination housing can be compared, but it is a cumbersome procedure suited only to detecting gross differences. Finally, for those nonrecipients who move to unmonitored structures, no comparisons are possible.

Although tracing the fortunes of individual families of nonparticipants has considerable intuitive appeal as a way of determining how they are affected by the allowance program, it is neither essential nor, we think, as productive for this purpose as the first two modes of analysis proposed above. These address the question of how nonparticipants as a group are affected, with relatively good measures of the effects. The alternative addresses the question of how individual nonparticipating households are affected, with weaker measures of the effects.

**Neighborhood Changes**

Whether or not the experimental allowance program significantly affects the cost of nonparticipants' housing, it may affect their
neighborhood environments. In some neighborhoods, the ethnic and social characteristics of the resident population may change as program participants move in or move out, thus altering the social milieu for nonparticipating residents. Housing improvements made by landlords and homeowners to comply with program requirements will often be externally visible and conceivably will be frequent enough to change the appearance of a neighborhood from shabby to spruce; other structures, left behind by program participants and not worth rehabilitating, may be boarded up or abandoned. Operating jointly, population changes and housing investment (or disinvestment) may be reflected in the cleanliness, safety, and social ambience of streets and public areas, neighborhood shopping facilities, etc.

Analysis of the effects on nonparticipants of neighborhood changes induced by the allowance program entails a series of difficulties. First, neighborhood changes must be observed systematically. Second, they must be attributed to the allowance program or else classified as independent events. Third, they must be shown to be matters of interest to nonparticipants. For some of the changes discussed above, all three steps seem feasible; for others, some steps are easy, others difficult or impossible. Below, we discuss the prospects as we see them.

Characteristics of Neighbors. Administrative records of the experimental allowance program will enable us to determine with precision how many households in a given neighborhood at a given time are program participants, how many moved there after enrollment, and how many left after enrollment. The same records will enable us to describe these households in terms of ethnicity, family composition, and income. Thus, we will be able to determine which neighborhoods experience an influx or an outflow of specified kinds of households as a direct consequence of the allowance program, and in which neighborhoods nonparticipants have more or less contact with such households than they had prior to the program.

Other population changes, involving only nonparticipants, will be less easy to measure. Our panel of monitored structures is not geographically stratified by neighborhood, and the tenants of the structures that are located in a particular neighborhood are not necessarily
a representative cross section of the neighborhood population. It is true that the sampling rate will probably be high in all neighborhoods containing substantial numbers of program participants at any time during the experiment; and it is also true that the sample of monitored structures and their tenants in a given neighborhood can be expanded, stratum by stratum, to represent the total neighborhood population of structures and tenants. Thus, in principle, we can use our sample data from successive annual surveys to estimate the net changes in the nonparticipating as well as the participating population. But we hesitate to rely generally on estimates prepared by this method.

In this situation, it seems most realistic to limit our plans. We can determine whether monitored nonparticipants in a given neighborhood have encountered more or fewer participants as neighbors, and how the characteristics of these participants differ from those of the monitored nonparticipants. These observations then become variables potentially influencing nonparticipant attitudes toward the allowance program, the analysis of which is discussed later in this section.

Housing Characteristics and Property Values. As explained above, records of the experimental allowance program will enable us to classify neighborhoods according to the incidence of program participants and changes in that incidence over time. If we are also able to observe neighborhoodwide changes in characteristics of the housing stock or in property values, these can be statistically associated with the changing incidence of program participants. If regular associations—either positive or negative—are visible in the data, it is reasonable to infer that the changes in housing characteristics and property values are effects of the allowance program.

Evidence of changes in land use, property values, and the characteristics and quality of the housing stock by neighborhood is available from three sources. First, our annual neighborhood surveys are designed to capture by direct observation the obvious changes in land use and in housing characteristics of each neighborhood, though not with precision. Second, our landlord (and to a lesser extent, our tenant and homeowner) surveys include a series of questions designed to elicit the respondents' perceptions of changing land uses, property
values, and housing characteristics. Third, the detailed data on structural improvements gathered in the landlord and homeowner surveys will give us good estimates of the amount and kinds of housing improvements that have occurred within each neighborhood's panel of monitored structures.

This last kind of information, while the most precise, is also the one whose generalization to the neighborhood level is most qualified by the sampling problems described above. Obviously, the case for neighborhood housing changes is strongest if all three data sources agree, and obviously agreement is least likely when improvements are few in number and scale. However, it is reasonable to anticipate that five years of monitoring will reveal unmistakable changes in some neighborhoods, for better or worse. As noted, we can connect these changes to the allowance program only by examining their covariance with the incidence of program participants. If that connection is clear in the data, we can then reasonably conclude that for nonparticipants, the program has changed their neighborhood residential environment in specified ways. How such changes may affect their attitudes toward the allowance program is explored later in this section.

Public Areas and Public Facilities. Changes in neighborhood populations combined with housing investment or disinvestment are often reflected as well in the ambience of public areas. However, the network of causation is complicated. Some changes in street life follow directly from population turnover—e.g., more or fewer children at play, different habits of waste disposal, carelessness or respect for public and private property, etc. Others are mediated by the public sector, which may respond to neighborhood changes with compensating or supportive changes in the level and type of services provided—e.g., more frequent trash collection, police patrols, capital improvements or neglect of neighborhood schools, street repairs, etc.

Many such changes will be observed in the course of the Supply Experiment. Our neighborhood survey requires the fieldworker to rate a variety of public facilities and services, and our household survey elicits the perceptions of respondents about neighborhood cleanliness, the quality of schools, public safety, etc. As with housing changes,
these observations can be statistically associated with changing incidence of allowance recipients, and thus with the allowance program. However, where a change in the level or type of public services is involved, the responsibility of the allowance program for the change is less clear.

Consequently, while we may be able to show that nonparticipants have been exposed to neighborhood changes of specified kinds, it is less likely that we can show that the allowance program is clearly responsible for those changes. However, the attitudes of nonparticipants toward the allowance program may be nonetheless affected by their experiences with neighborhood change if they make (correctly or incorrectly) the causal inferences about which we feel cautious.

Nonparticipant Mobility

In the preceding pages, we have discussed ways in which the availability and cost of housing for nonparticipants may be affected by the allowance program, and how their neighborhoods may change as a consequence of relocation by participants and associated changes in the housing stock. In response to such events, nonparticipants may readjust their lives without changing residence, or they may themselves move to different neighborhoods to escape what they regard as undesirable changes in their previous housing or neighborhoods.

At one end of the spectrum of possibilities, inflation in the price of housing could force some nonparticipants into worse housing or less desirable neighborhoods. At the other end, some may decide that shifting from rental tenure to homeownership in a different neighborhood, even at greater total cost, is preferable. It is also conceivable that allowance-induced changes in the housing market may persuade some nonparticipants who might otherwise have moved to stay where they are. At this point, we can only speculate about the relative weights of various push/pull factors and how they might affect the redistribution of nonparticipants by neighborhood, tenure, and general housing circumstances.

In Sec. VIII, we explain how our program of annual field surveys addressed to the tenants of monitored structures will provide data
enabling us to assess the effects of the allowance program on patterns of movement by both participants and nonparticipants. Combining retrospective and current data on mobility and on the circumstances associated with changes of residence, we expect to be able to show how the allowance program affects the frequency and directions of movement and at least some of the relationships between the characteristics of origin and destination housing and neighborhoods. As we note in Sec. VIII, the analysis is improved by following nonparticipants when they move, but data on postenrollment moves by nonparticipants can, if necessary, be obtained by retrospective questioning of those who move into monitored structures.

Effects on Special Groups

There are several groups within the nonparticipating population whose fortunes under the allowance program are of special policy concern. Chief among these are the elderly, the poor, and ethnic minorities—groups generally conceded to be least able to cope with price inflation, dislocations in the housing market, or undesirable changes in their residential neighborhoods.

We expect these groups of nonparticipants to include many individuals and households whose lack of resources would justify housing assistance under our program standards. Some, like unrelated individuals under 62 years of age, are statutorily excluded. Others who are eligible may fail to apply or decline to enroll when they understand what is required of them. Thus, an elderly couple owning a dilapidated home and living on Social Security would be entitled to assistance only if they sold their home and moved to certifiable quarters, a step they may be unwilling to take. Still others may have incomes that enable them to afford adequate housing, but they may be particularly immobile (e.g., the elderly) or may face particularly limited opportunities in the housing market (e.g., blacks).

Thus, in pursuing the various impact analyses described in the preceding pages, we plan wherever possible to isolate these groups for special analysis, contrasting their experiences with those of the general run of nonparticipants with respect to changes in housing costs
and availability, neighborhood environments, and mobility patterns. The principal limitation on such analyses will be sample sizes, which may be too small to allow separate treatment of all the special groups of interest.

**ATTITUDES OF NONPARTICIPANTS**

The design of the experiment provides for measurement and analysis of various effects of the allowance program on nonparticipating households. Even if those households are not substantially affected, however, they may well believe their situation has changed as a result of the program, either because some other forces have been operative at the same time, or because their subjective assessment has misled them.

Consider the probable reaction to any increase in the price of housing during the course of the allowance program. We can expect housing costs to rise during the course of the experiment from background inflation, if for no other reason, but we also expect some allowance-caused price inflation in the early stages of the experiment. We are prepared to separate out the allowance-caused portion by analysis of the experimental results. However, a valid finding that the price rise was primarily due to background inflation could well get a skeptical reception from those accustomed to relying on their own interpretation of events or those who resent the allowance program for other reasons.

A similar point can be made about population movements. We expect some moving to result from the experiment as households attempt to qualify for the allowance by locating new quarters of certifiable quality. However, much moving occurs anyway, particularly in the low-income segment of the population. This background moving may well have a pattern that attracts notice, and nonparticipants may erroneously attribute it to the experiment. Again, our analytical techniques will enable us to separate the two components, but we can only guess at how the population at large will interpret such developments.

Such opinions and attitudes will constitute a particular sort of appraisal of the experiment. We need to be informed of these opinions
and attitudes, both because we wish the experimental findings to meet
the arguments of such informal assessments and because the attitudes
and feelings of the population involved may guide us to features of
the experiment that are producing some gratuitous impression or irri-
tation. We can identify four major areas of interest: what nonpartici-
pants think about the allowance program; the views of nonparticipating
eligibles toward the program and why they failed to enroll; how non-
participant attitudes toward the poor, minority groups, landlords, the
government, etc., change during and as a result of the program; and
what kind of overt action or expression toward the program or the
issues can be expected—if any. Treatment of these topics entails
survey work beyond that contemplated by the experimental design, up
to this point. We will consider the importance and the difficulties
of each of the areas in turn, after addressing some methodological
questions associated with attitude surveys.

Methodological Issues

A basic problem with the measurement of attitudes (in comparison
with economic or demographic data) is the serious risk of erroneous
measurement resulting from the measurement process itself. The more
sensitive the respondent feels a topic to be, the more obtrusive these
problems become. The list of hazards is well known: social desirabil-
ity effects, halo effects, response sets, and equivocal answers given
by the respondent because of his perception of the interviewer’s ex-
pectations. There is also a serious risk of creating attitudes toward
objects or situations about which the respondent lacks knowledge.

Such considerations lead to several conclusions about our approach
and analysis:

1. The best way to measure sensitive attitudes is by indirection,
that is, by seeking reactions to statements that do not ob-
viously require the respondent to express his prejudices about
such factors as race. One particularly appealing method uses
information tests to diagnose attitudes. For example, attitudes
toward the recipient population might be probed by a multiplechoice question about the average amount of the monthly hous-
ing allowance payment for a female-headed household with two
children. At least one choice would be decidedly too low, and
another would be too high, relative to the correct amount; the
correct amount would also be offered as a choice. The
direction of the respondent's error in response to such a
question is taken as an indicator of his attitude toward al-
lowance recipients.

2. If we are to interpret the attitudinal data we obtain, we
must relate attitudes to other variables such as the follow-
ing: education, level and type of organizational activity, income,
and the racial and class composition of the block in which the
respondent resides; the amount of his contact with
program participants; and his relationship to them (neighbors,
close friends, relatives).

3. In addition, we need to find out what nonparticipants know
about the program in order to interpret their attitudes toward
it as a joint function of their knowledge and their exposure
to its effects.

Attitudes of Nonparticipants Toward the Allowance Program

Of highest priority in our concern about nonparticipants is our
need to sense and weigh the development of local opposition to the
allowance program. Nonparticipants will not directly benefit from
the program and, partly because they will realize such schemes are tax-
financed, may easily perceive disbenefits for them. That they do not
receive direct benefits does not mean that they will not, eventually,
realize some indirect ones in the form of generally upgraded housing
and related community improvements. Whether these are felt at all by
the nonparticipants will have to be discovered by asking them.

Attitude and reality can be related in several ways. The respon-
dent may perceive the effect of the allowance program on his interests,
favorably or otherwise, more or less correctly, or he may make either
of two errors in perception, loosely analogous to the Type 1 and Type
II errors of statistical inference. The program might in fact have
a detrimental effect on nonparticipants' housing costs or environment,
but respondents might not attribute the effect to the program; al-
ternatively, the program may have no adverse effects (or may even
confer benefits), while nonparticipants have the impression that it
does affect them adversely.* The latter possibility may be more
likely, and it is the one that motivated our initial concern with at-
titudes. The other is also potentially important. We could not count
on nonparticipants in future programs to similarly overlook the programs'
drawbacks to them, and we thus might considerably underestimate future
implementation difficulties.

We wish to know what attitudes nonparticipants hold toward the pro-
gram, how attitudinal differences vary with the respondent's situation,
and how these attitudes were formed. Therefore, using appropriate
multivariate methods, we shall attempt to relate our attitudinal in-
formation to the major socioeconomic characteristics of the respondent
(including neighborhood and housing); the amount of exposure he has
had to the allowance program, particularly his contact with participants
as evidenced by their incidence in his neighborhood; his more general
fund of knowledge about the program; his fund of knowledge about hous-
ing--rent control, landlords' costs, property values; and his exposure
to events and circumstances--neighborhood change, housing difficulties,
price inflation--that may not be related to the program but could be
so interpreted.

Various groupings of nonparticipants may prove to be of analytical
importance. For example, attitudes may vary according to the housing
submarket in which the respondent is found: those who competed for
housing with eligible households before the allowance program began;
those in the same submarket with program participants after the pro-
gram began; those who do not compete in the same market but may feel
an induced effect on rents or prices; and those who are not, as hous-
ing consumers, affected at all by the program. Equally, groups of

* A view of the program impact that has the proper sign but exag-
gerates the magnitude is another possibility, of course.
special policy concern, such as the elderly, unrelated poor persons under 62 years of age (who will not be eligible for allowances), and racial and ethnic minorities are important to examine separately.

Survey Tactics

There is clearly a strong case for gathering data on attitudes toward the allowance program after it is in operation. We see much less to be gained by pursuing this issue in the preenrollment period, when respondents can only react to advance publicity about the experiment. Consequently, we have made no provision for such questions in our baseline survey instruments, other than some general inquiries about how expenditure patterns would be affected by specified changes in income.

There are two ways of acquiring the necessary information in the postenrollment period: We can incorporate attitudinal questions in the survey of households living in the monitored structures, or we can administer an independent survey to a random sample of other households. The former procedure would avoid the cost of designing the sample and administering a separate survey, and it would take advantage of some relevant questions already included (chiefly, those asking for socio-economic information from the responding households).

An independent survey would also have significant strong points. It would avoid loading more topics into our already rather lengthy survey instrument. It would avoid, or at least permit controlling for, the (probably small) possibility that attitudes toward the allowance program might be contaminated by repeated surveying or by residence in a monitored structure.* Finally, an independent survey would give us a free hand in designing an appropriate sample. Our sample of structures is intentionally weighted toward sectors of the market that are likely to contain program participants, with very low sampling rates in large sectors of the market within which we expect to find

* A partial counter to this objection is that new nonparticipants will presumably appear in the sample structures as the experiment proceeds. However, we should be cautious about assuming that new nonparticipant move-ins will be as numerous as we would like for this purpose.
only nonparticipants. While this sample directs our attention to non-
participants who are most directly affected by the program, it tends
to ignore those more likely to be influential in community affairs.

We are not now sure which arguments should prevail. Because no
information must be obtained at baseline, a final decision need not be
made until well into the first year.

We might also note that the resident observer can play an impor-
tant role in sensing and interpreting attitudinal developments. Aware
of the context of local and national events in which these developments
take place, and the character of the channels through which they are
articulated, a sensitized individual will be able to discern, and diag-
nose the impact of, shifts in public attitude in ways that cannot be
done with survey data alone.

**Attitudes of Those Eligible but Not Participating**

The eligibles who choose not to enroll comprise a subgroup of non-
participants of particular interest. Do these respondents have an
accurate understanding of the program? Does the program have draw-
backs for them that are not now foreseen? Will we find significant
attitudinal or social barriers to participation? Do respondents feel
that enrollment would be stigmatizing or threatening to their personal
liberty? Would acceptance of the allowance involve reducing other ex-
penditures, by virtue of the higher cost of certificated housing (after
all, some are now receiving housing free or in exchange for services)?
Are the benefits simply not worth the trouble?

The variety of possible explanations, all conjectural at this
stage, underscore the importance of exploring the subject of nonpartici-
ipation. By use of the baseline survey, we will be able to tell, with
sufficient accuracy for present purposes, which households in our mon-
tored structures are eligible for the allowance program. Reference
to program enrollment records will, in turn, reveal which ones did not
sign up for the allowance. These households constitute an entirely
suitable sample panel to whom the relevant questions about their situ-
ations and attitudes can be addressed. We can then assess the relative
importance of attitudinal factors and other circumstances—housing, economic, or informational—to the choice not to participate.

No additional baseline data will be required for this analysis.

**Attitudes Affected by the Allowance Program**

In addition to learning about public reactions to the allowance program, we might also try to discover how the allowance program may affect other social attitudes, e.g., attitudes toward the poor, the welfare system, racial minorities, landlords, the government. If such effects occurred and could be traced to the allowance program with fair confidence, useful purposes—even important ones—might be served.

However, we have no particular reason to expect the program to be so prominent as to greatly affect peoples’ views about these related (or relatable) matters. We are concerned, moreover, about the feasibility of establishing causality between contact with the allowance program and shifts in attitudes about other things, even related things. Attitude formation is a complex process, and attitudes will be modified, slowly or however, by a variety of forces. Since we do not think the allowance program is likely to have a very large effect on peoples’ views of social issues, we conclude that the odds are low that analysis of the connection between the allowance program and changes in these views would be fruitful.

Furthermore, an interest in comparing attitudes before and after the allowance would require prompt action to mount the appropriate survey before or at the start of the program. These considerations together lead us to recommend that this topic not be included in the survey.

Not including such questions in the survey does not mean that we must lose all interest in the subject, however. As indicated above, the resident observer will be alert to attitudinal developments. It seems unlikely that a major reaction of the type that concerns us in this subsection could completely escape his notice.
Attitudes and Action

We are also concerned about the nature of antiprogram activity that may develop in the community. The effectiveness of citing systematic surveys for "representative" attitudes in the face of an outspoken reaction can be blunted if even a tiny minority with negative attitudes can mobilize organizational or influential support. Alternatively, even a substantial minority of nonparticipants having negative attitudes toward the program may lack a constructive outlet for their reactions. In such an event, it may be in the interest of the program to supply one.

One useful relationship to explore is that between attitudes toward the allowance program and organizational affiliations. The latter provide clues to nonparticipants' potential leverage in influencing community opinion. Such information will therefore be sought as part of the postenrollment surveys of nonparticipant attitudes that we recommend.

In addition to (and in between) these surveys, our resident observer will make it his business to talk informally with community leaders and members of influential organizations comprised of nonparticipants, and to attend meetings of civic or fraternal organizations where the housing allowance program might be discussed. His role will not be to defend the program, but to gather intelligence. If this is done with skill and diligence, we will be alerted not only to changes in the tone of public opinion, but to the emergence of organized opposition.

In sum, even if the effect of the program on community housing standards is favorable, there may develop organized opposition either to the experiment (with all its field surveys) or to the allowance program. As managers of the experiment, we shall have to deal with such opposition as best we can, seeking to pacify it without misrepresentation. As advisors to HUD, it will be our responsibility to pinpoint, if we can, specific features of the experimental allowance program that provoke opposition, and to suggest, if we can, modifications that would lessen these difficulties in the case of a national program. The study of nonparticipant attitudes is part of the machinery for doing this.
X. INFERENCE FROM EXPERIMENTAL FINDINGS

In the preceding sections of this report, we have set forth our recommendations for the design of an experiment whose purpose is to gain information about the probable consequences of a national program of housing allowances. This information is needed both to shape the design of a legislative proposal for such a program and to inform the judgment of those who must decide whether, on balance, the proposal is in the public interest. As noted in Sec. II, the results of this experiment must be intelligible and convincing not only to professional economists and housing experts, but to the broader constituency whose support would be essential to passage and implementation of a national program.

Here, we shall try to evaluate the reliability and credibility of inferences drawn from the proposed experiment as guides to the effects of a national program. We shall also try to show how the findings of the Supply Experiment can be analytically linked to those of the Demand Experiment, and we discuss the problems of inference from the joint results.

GENERALIZING FROM EXPERIMENTAL EVIDENCE

Basically, the plan of the Supply Experiment is to mount a full-scale housing allowance program in each of two small metropolitan areas and monitor its consequences: changes in the price and quantity of housing services supplied by the market, the behavior of indirect suppliers and market intermediaries, residential mobility and neighborhood changes, effects on and attitudes of nonparticipants. The most intensive monitoring efforts are planned for a sample of residential properties, their landlords, and their tenants, concentrated in those sectors of the housing market most likely to be affected by the program; and for program participants, who will be followed as long as they are enrolled. Monitoring is scheduled to last for five years after commencement of the allowance program.
Can we reliably infer from the evidence thus produced what would happen in response to a national program of housing allowances? It is helpful to distinguish six reasons why this experimental evidence might lead to erroneous general conclusions:

1. The estimates and measurements made during the course of the experiment in these two metropolitan sites may be inaccurate.
2. Consequences attributed to the experimental allowance program may be due to other factors, or the reverse.
3. The consequences of an experimental allowance program may differ from the consequences of a "real" program of the same design.
4. The consequences observed in the two metropolitan sites may be unrepresentative of those that would occur in other metropolitan (or nonmetropolitan) areas.
5. The term of the experiment may be too short to observe important long-run consequences of an allowance program.
6. Consequences may be so closely linked to the specific provisions of a housing allowance formula that tests based on any one formula would have little relevance to other formulas that might be chosen for a national program.

We have thought a good deal about these issues, with the result that many specific features of our proposed experimental design were included to avoid or reduce the likelihood of erroneous inferences about matters of importance. On most of these issues, we think either that the experiment will be self-validating—i.e., that analysis of experimental findings will enable us to judge the reliability of inferences from them—or that the path to greater reliability is clear, the principal obstacle being its incremental costs. Below, we offer our conclusions on each issue.

Errors of Estimation and Measurement

Our monitoring plan includes field surveys to gather quantitative data on residential properties, their owners, and their tenants; the
use of administrative procedures to gather data on program participants; and informal monitoring of local attitudes and events bearing on the allowance program. Data gathered by all three means are subject to error.

Our field surveys will follow a sample of residential properties for the duration of the experiment. The sampling frame is designed so that properties moving into or out of residential use during the monitoring period will also be captured. The sample is stratified by housing characteristics that differentiate major sectors of the housing market; the sampling rates vary among the strata, with the bulk of the sample elements drawn from sectors of the market that we think are likely to be directly affected by the experimental housing allowance program. The probability that any given residential property will be included in the sample can be calculated, and all such probabilities are greater than zero.

By applying inverse probability weights to observations made on the elements of our sample, we can estimate the incidence of an observed characteristic in the universe from which the sample was drawn—i.e., in the housing stock of the geographically bounded experimental site. Such estimates are possible not only for the physical and financial characteristics of the residential properties that are surveyed, but also for the characteristics of their owners and their tenants.

However, such estimates are subject to sampling errors whose magnitudes cannot be determined precisely in advance, since they depend in part on the actual distribution of values of the characteristic for which the estimate is made. Our sample design is keyed to the problems of estimating stratum mean values of a particularly slippery parameter, the price elasticity of the supply of housing services. Our a priori calculations indicate that for those strata of the housing market likely to be substantially affected by the allowance program, sampling error will be small enough so that we can tolerate equal amounts of error from other sources without destroying the usefulness of the estimates for policy analysis. For less complex measures—e.g., the number of resident landlords, the average fuel expenditure per unit, the number of female-headed households, the percentage of households dissatisfied
with their housing—sampling errors should present no serious obstacles to a reliable description of the universe, or at least of that portion of the universe which is significantly affected by the allowance program.

We do need to worry about nonresponse bias and about erroneous or misleading responses in field surveys. The household surveys pose no novel problems in these respects, and there are well-developed quality-control techniques to deal with the problems we do anticipate.

We anticipate more difficulty with the field survey of building characteristics and condition, which relies on direct observation by the fieldworkers. Here, our task is to devise a field instrument that will reliably capture changes in building condition from one annual survey to the next; we have little hope of devising one that will enable us to make rigorous comparisons among buildings. Because of these anticipated difficulties, our analysis plan does not rely heavily on the building survey.

We think that the key to the success of the Supply Experiment will be our ability to obtain from landlords honest and accurate reports on their maintenance and operating outlays and the costs of capital improvements. Experience with this type of survey is limited. We know of several instances in which public-housing authorities, nonprofit-housing sponsors, or building-management firms have been able and willing to supply researchers with well-documented financial records on individual structures or housing projects. But we know of only one survey, conducted in New York City, that was addressed to a large number of small holders and sought the kind of financial data we must collect.*

Considering that this survey was conducted under the sponsorship of the Office of Rent Control in a tense political environment, it was surprisingly successful. We have reviewed the field instruments and operating procedures, studied the incidence of nonresponse, and worked with the reported financial data, comparing them with audited data from

---

* The survey and its findings are reported in George Sternlieb, *The Urban Housing Dilemma: The Dynamics of New York City’s Rent Controlled Housing*, issued in draft form by the Department of Rent and Housing Maintenance, Housing and Development Administration, City of New York, May 1970.
nearly the same universe. We think we have a better-than-fighting chance of obtaining the information we need to measure supply responses within tolerable error limits.

But we have gone to considerable pains to design the experiment and plan the data analysis so as to allow latitude for measurement error. Here, we rely on three principles: powerful experimental "treatments," aggregation, and redundancy. Our use of these principles is described below.

On purely definitional grounds, it is clear that the supply response to a housing allowance program cannot be greater than the incremental housing expenditures that result from the program, i.e.,

\[
\frac{\Delta B}{N} = \frac{\Delta \bar{x}}{\bar{x}} + \frac{\Delta \bar{y}}{\bar{y}} + \frac{\Delta \bar{x}\bar{y}}{\bar{x}\bar{y}}
\]

If \( \Delta B/\bar{x} \) is large, we can be sure that either \( \Delta \bar{x}/\bar{x} \) or \( \Delta \bar{y}/\bar{y} \) or both will also be large. With a given error of measurement, the relative accuracy of our estimates of price and quantity changes increases with the magnitude of the changes. It is for this reason that we insist on focusing our monitoring on sectors of the market with a high incidence of allowance recipients, where we can be sure that \( \Delta \bar{B}/\bar{x} \) will be large.

We have planned our analysis of supply responsiveness so that the principal conclusions are derived from aggregate values for market sectors rather than from values for individual structures. Such aggregate values are relatively insensitive to randomly distributed measurement errors for individual structures. But we have also planned the analysis in terms of relative changes, which means that its conclusions are insensitive to biased errors of measurement as long as the bias is consistent over time.

Finally, we propose to supplement our central analysis of supply responsiveness based on landlord financial reports with two less rigorous collateral measures: changes in directly observed building condition, and changes in tenants' evaluations of their housing. If these collateral measures seem to contradict the evidence of our financial
measures, the credibility of the latter is obviously weakened. In a five-year monitoring program, there is time for corrective feedback from such signals of trouble.

Netting Out Background Effects

A potential difficulty in interpreting our experimental findings is that of distinguishing events caused by the experimental allowance program from those that would have happened in its absence. There are two classical methods for isolating the effects of an experimental treatment. One is to match the treated population with an untreated "control" population, ascribing the differences in the subsequent histories of the two populations to the treatment. Another is to apply the treatment to a system that is in equilibrium, sheltering it from any other exogenous influences during the term of the experiment. Unfortunately, neither of these methods can be applied to our experiment.

The first method will be used in the Demand Experiment, where the experimental unit is the household. But in the Supply Experiment, the experimental unit is a metropolitan housing market. While it is true that individual households are "treated" by giving them housing allowances, our interest lies less in their individual responses to this treatment than in the effect on the metropolitan housing market of a large infusion of low-income housing demand. To make a statistical comparison of treatment and control groups, we would need to mount the housing allowance program in a randomly selected subset of all metropolitan housing markets and monitor a similar subset as a control group. Considerations of cost, if nothing else, rule out this approach.

It would not even be very helpful to select two metropolitan housing markets, each matched to one of our experimental sites, as control cases. For a control case to be matched with a treated case implies not only congruence of baseline characteristics, but congruence of demographic and economic forces (other than the allowance program) operating on each site throughout the term of the experiment. Achieving congruence of the first kind would be difficult enough; guaranteeing congruence of the second kind, before the fact, would be impossible.
The second classical method of experimental control is equally difficult to implement for our experiment, but we will nonetheless have to rely upon it in part. In selecting sites for the Supply Experiment, we have tried to avoid metropolitan areas whose housing markets have suffered recent severe dislocations, and those in which such events seem likely over the term of the experiment. In other words, we seek to conduct the experiment in a semi-equilibrated environment, where the "natural" forces affecting the supply and demand for housing are changing according to some regular pattern that can be extrapolated with reasonable confidence.

But whatever our success in choosing housing markets with these properties as experimental sites, we are unable to guarantee that they will be free of exogenous shocks during the term of the experiment. We will have some control, with respect to Federal housing and urban-renewal programs; but we cannot prevent natural disasters or large-scale private actions that would dislocate the housing market (such as the opening or closing of a large manufacturing plant).

We think that it is important to recognize the real possibility that a major shock to the metropolitan economy could play havoc with our experiment. By careful site selection, we can reduce the possibility of such an event; with luck, we will escape its occurrence; finally, with two experimental sites, the odds are very high that at least one will not experience such a dislocation.

Within the context of such a semi-equilibrated housing market, we must and can reasonably rely on analysis to distinguish the effects of the allowance program from the effects of other factors. The techniques of analysis and the assumptions they entail vary with the effect to be analyzed; but generally we rely on one or more of three methods:

* Technically, this situation can be described as a dynamic equilibrium, in which rates of change for the variables of interest are stable over time—e.g., 2-percent annual increase in population, 5-percent annual increase in income per capita. It contrasts with a stable equilibrium, in which rates of change over time are zero.
1. Comparing circumstances and behavior during the experiment with corresponding circumstances and behavior prior to the experiment.

2. Comparing the circumstances and behavior of those most directly affected by the allowance program with the circumstances and behavior of those for whom the connection to the allowance program is remote.

3. Modeling events in the housing market with and without allowances, using the same behavioral parameters for both cases.

Thus, our proposed analysis of the effects of the allowance program on residential mobility relies on Methods 1 and 2, with a four-way comparison of the behavior of program participants and of nonparticipants, before and after the commencement of the allowance program. Our analysis of the effects of the allowance program on the price and quantity of housing services relies on Methods 2 and 3, comparing sectors of the market in which allowance recipients participate with those from which they are absent; and modeling the aggregate effects on supply of income and housing demand shifts for participants and nonparticipants separately.

Finally, to the extent that we are unable to disentangle the effects of the allowance program from other factors at work in the local housing market, we should be able at least to reach a fortiori conclusions of a type that have considerable power in policy analysis. That is, we can conclude that the effect of the allowance program on Variable X was at least (or at most) such-and-such. So long as there is continuity with preallowance time in the behavior of background forces, the inseparable background changes should be small relative to allowance-induced changes in the housing market.

Experimental Response Versus Program Response

The Housing Assistance Supply Experiment differs from a national housing allowance program in several ways. First, the experiment will enroll only those eligibles who live in the two selected metropolitan areas at the time enrollment is opened, and those who leave these areas
will be dropped from the rolls. Second, the experimental allowance program is of limited duration; we have proposed a ten-year commitment. Third, participants in the local housing market will be aware that their behavior is being monitored, and that the future of a national housing allowance program may well depend on the monitors' conclusions.

In an earlier version of the experimental design, when we proposed to limit enrollment to residents of selected low-income neighborhoods, the first of the differences noted above loomed large. The implied restrictions on the local mobility of experimental allowance recipients were seriously inconsistent with the probable rules of a national program, and the results of the experiment could thus be misleading. The present design, with enrollment expanded to include all eligible residents of the metropolitan area, quieted this concern. Within the limits of their allowance-augmented budgets, participants may select their housing from the full variety offered by the local housing market. Restricting eligibility to those in residence at the beginning of the program precludes allowance-motivated migration into the metropolitan area; in a national program, there would be no such motive for inter-metropolitan movement.

The one remaining difficulty is that under these rules the number of program participants may decline over time due to outmigration without replacement. This could be a serious problem, since the normal rate of low-income outmigration from a single-county SMSA is about 7 percent annually; however, the experimental allowance program may reduce this flow, since recipients who leave will lose their benefits. If we do encounter serious depletion of our panel of recipients, we have the option of opening enrollment to recent arrivals—without promising to accommodate future arrivals.

As long as we select metropolitan sites for the Supply Experiment that are "free-standing"—i.e., separated from other population concentrations by an expanse of thinly populated territory—it is manifest that cross-elasticities of housing demand between our sites and other local housing markets will be trivial: We do not need the background of a national housing allowance program to produce its demand consequences
at a local level. Cross elasticities of supply are more problematical, since some of the resources required to produce housing services are intraregionally mobile. If we observe a large influx of outside resources (e.g., remodeling contractors) in response to local demands for housing improvements, we ought to be cautious in our inferences from the experiment as to the inflationary effects of a national program; factor-price inflation observed at the experimental site is likely to be an underestimate for a national program. But unless the experimental program's demand impact is at least twice as great as we anticipate, significant intraregional factor movements seem to us highly unlikely.

The second point on which the experimental program contrasts with a national program is its expected duration. This is important because present behavior of both housing consumers and suppliers is governed by their expectations about the future. An allowance-eligible household would hesitate to move, or to sign a long-term lease at a higher rent, or to shift from rental to ownership tenure if it expected the allowance to be withdrawn soon after its action. A building owner would hesitate to make capital improvements whose amortization depended on allowance-stimulated revenue increases if he expected the allowance program to terminate soon thereafter.

Although we propose to monitor the experiment for only five years, we cannot overstate the importance of a longer commitment for the allowance program: we think ten years is the minimum that should be considered. For eligible renters who wish to purchase a home, we have proposed life-of-the-mortgage assistance commitments under Sec. 235. For homeowners who must make capital improvements to qualify for assistance and for renters who are considering allowance-assisted moves or rent increases on their present units, we feel certain that a ten-year assistance guarantee (contingent on continued eligibility) would be adequate to motivate the behavior that would accompany the permanent guarantee of a national program. For landlords, we think a ten-year guarantee is the minimum.*

*We are not proposing to guarantee each landlord a specific increase in revenue for ten years--only that the allowance program will
The mathematics of debt service tell us that if a landlord must amortize capital improvements over five years versus their expected life of 21 years, the annual cost to him is nearly tripled. We estimate that to cover the increased debt service costs, averaged in with other housing inputs, he would typically have to raise rents by 12 percent more than he would under a 21-year amortization program. If amortization were reduced from 21 to 10 years, he would need only 4 percent more rental revenue to cover his added costs.*

The third problem of experimental bias is the so-called Hawthorne effect. Participants in the Supply Experiment may behave differently than they would under a national housing allowance program simply because they are aware that it is an experiment. Tenants and landlords in our sample of residential properties will not only be aware that the program is experimental, they will be aware that their own actions are being closely monitored in a way that would not be characteristic of a national program.

The problem here is particularly acute for landlords whose operations are monitored. Annual surveys of building condition, maintenance and operating outlays, capital-improvement costs, and rental revenues will make the landlord aware that the monitors of the experiment can estimate whether he is profiting unduly from the allowance program. The survey instruments and field procedures will be designed to muffle the issue of landlord profits—e.g., we will not inquire directly about them—and those who are doing poorly will not hesitate to tell us so. But those who are doing well are likely to be troubled by the implications for them of revealing this fact.

We would be surprised to discover that actual property-management decisions were much influenced by the monitoring program. More likely in our view would be misrepresentation or refusal to cooperate with

continue to generate effective demand for that period. It is then up to the landlord to capture his share by making whatever improvements will attract allowance recipients.

*This brief exposition is less than satisfactory. See Lowry, Rydell, and de Ferranti, op. cit., WN-7711-U1, pp. 55-57, for a more adequate account of the calculations that lead to these conclusions.
interviewers.* Thus, while the real outcome of the experiment would not be much affected, our comprehension of that outcome could be. Our main protection is careful survey procedures and cross-checking of data to alert us to inaccurate responses.

We should note that periodic interviews with allowance recipients and certification of eligible structures are planned as administrative procedures that would be necessary elements of a national program: in the experiment, the interviews and building inspections may be a bit more elaborate than would be necessary and probably more careful than would be typical of a national program. We see no reason to anticipate serious experimental bias from this source.

Uniqueness of Experimental Sites

When the Supply Experiment is considered as a basis for generalization about the probable consequences of a national housing allowance program, the unit of observation is not the individual property or household but the local housing market. Within each experimental site, we may be able to detect characteristically different response patterns for classes of individuals, but all responses may be significantly influenced by the configuration of the market: its size, the compositional characteristics of its household population and its housing inventory, its cultural and economic geography, and its history.

Metropolitan areas of the United States vary considerably in these respects. Given a sample of only two such areas for the Supply Experiment, what can we say about the probable effects of a national program in other places?

Clearly, the usual methods of statistical inference are not helpful here. But we see two ways of guarding against unwarranted generalization: careful selection of the experimental sites, and structural analysis of the experimental findings.

Our plans for site selection are detailed in a separate report.**

* The screening procedures are complex, but basically we seek two

** Housing Assistance Supply Experiment Staff, op. cit., WX-7833-HUD.
metropolitan areas that differ in ways that are likely to affect the outcome of the Supply Experiment. The characteristics that we think are critically important are central-city growth rate and the ethnic composition of the central-city population. Second-order characteristics are the incidence of rental tenure and multiple dwellings in the central-city housing inventory, and the central-city vacancy rate. Third-order characteristics are unemployment rates, welfare incidence, and poverty incidence.

Our focus on central-city characteristics reflects their greater variability among SMSAs. The particular characteristics we have selected and their weighting reflect educated judgment and the availability of 1970 Census data. Roughly speaking, our screening procedures lead us to select upper- or lower-quartile values for the characteristics of interest, bracketing the center of the SMSA distribution. Thus, our two experimental sites should be distinctively different, each representing a well-populated subset of the universe of metropolitan areas.

If experimental outcomes in these two sites are similar in all respects that are important for the evaluation of a national housing allowance policy, we think most people would agree that generalization from the experiment is reasonable despite the inapplicability of statistical tests. If the experimental outcomes differ substantially, we must be more cautious in our generalizations.

In the latter case, structural analysis may help. Given different outcomes, can we account for the differences in terms of the characteristics of our sites? This is a difficult assignment because of covariance among the characteristics. But by combining housing-market theory with our observations of the dynamics of the experiment at each site, we should be able to develop reasonably sturdy hypotheses about the critical factors at work. Then, by examining the incidence of these critical factors in the universe of SMSAs, we can estimate which are likely to respond in the pattern of Site A and which in the pattern of Site B.

The technique is helpful but not foolproof. There may be relevant market response patterns not encountered in either of the two experimental
sites. Our structural analysis is not subject to independent validation, though partial checks may be possible. But it seems clear to us that the information gathered from even two case studies is much better than no information at all. At a minimum, we can cast light on the prospects of a national allowance program in places that resemble the two experimental sites, and these will be numerous.

We are least comfortable about the issue of SMSA size. For reasons of economy, the experiment is to be mounted in small SMSAs, with fewer than 250,000 inhabitants. Yet the most critical housing problems are generally acknowledged to be in large SMSAs, where ethnic ghettos are extensive and the incidence of rental tenure in multiple dwellings is high. We recommend to HUD that it consider a third experimental site, consisting of a low-income neighborhood in a large metropolitan area, with enrollment in the allowance program restricted to that neighborhood.*

Duration of the Experiment

Earlier, we discussed the effects of limited duration on the expectations of allowance recipients and property owners. Here, we are concerned with a different issue: whether the supply response to a sudden increase in effective demand would work itself out to a new and stable equilibrium within the five years allowed for its observation.

There is little systematic information about response lags in the housing market, but informed observation leads us to think that a sudden change in demand is generally reflected in rents within about a year, and in output changes within two years, except for new construction and major capital improvements. We think that five years is certainly adequate to observe most of the changes that would occur.**

Moreover, we think that the policy relevance of information gained from a longer monitoring period would be slight. Within five years, either a national housing allowance program will have been proposed and

** See Lowry, Rydell, and de Ferranti, op. cit., WH-7711-UI, pp. 48-53, for our scenario of the dynamics of an allowance-stimulated market.
passed into law, or it will have been decisively rejected. Insofar as the design and decision are based on experimental evidence at all, it will be on the evidence from the first few years of the experiment. Later findings may come in time to modify such a program if its principle has been accepted, but they would be unlikely to revive it if its principle has been rejected.

In any case, a firm decision about the duration of the monitoring program need not be made a priori. As data from the early years of the experiment are analyzed, we will acquire a better grasp of market response than we now have. We will also discover new issues pertinent to a national housing allowance program, for which no monitoring provisions have been made. Clearly, as we gain experience, we should reconsider not only the duration but the content of our monitoring program.

**Supply Response Under Different Allowance Programs**

We have designed an allowance program for the Supply Experiment, and we plan to apply the same rules to all participants at both sites. Briefly, we propose to issue rent certificates to all eligible renters, for use in partial payment of rents in certified structures; to provide equivalent mortgage interest subsidies to eligible home buyers; and to assist homeowners by monthly contributions channeled through a third party. Except for special restrictions on eligibility that may be imposed by law on the funds used for the experimental program, eligibility and the amount of the allowance are determined by the same factors: the applicant's disposable income, the size of his household, and the local cost of a defined level of housing consumption. The details are presented in Sec. III.

The allowance formula operates on the "housing-gap" principle; that is, the amount of the allowance for each household is set so as to enable the household to afford a specified level of housing consumption without unduly restricting other consumption.

We have no guarantee that a national program of housing allowances would follow either our rent-certificate format or our particular
variant of a housing-gap allowance formula. Alternatives to both are under active consideration. Can the results of the Supply Experiment, based on a specific allowance program, be generalized to apply to other variants of the housing allowance concept?

It is helpful to divide the issues. With respect to the demand response to housing allowances, the terms and conditions of the specific allowance program are manifestly critical. This issue is to be explored by the Demand Experiment. With respect to the supply response, the specific allowance formula is less critical: what counts is the result—i.e., the amount of the increase in housing expenditures, and variations in this increase among households. Finally, any special restrictions imposed on the use of allowances could be important if they focused allowance recipients' demands on a particular class of structures.

We think that the issue of the dependence of supply response on the specifics of the allowance formula can easily be overinflated. Most of the variants in housing allowance formulas are matters of more or fewer eligible households, higher or lower levels of payments, and more or less freedom for households in allocating assistance payments between housing and other goods. For a given experimental site, different allowance programs would lead to somewhat greater or somewhat smaller increments in demand for housing, and some variation in the distribution of this incremental demand among households of various sizes and incomes.

So long as it is possible to estimate, for a given allowance formula, its effects on housing demand, it should also be possible to estimate from the data gathered in the Supply Experiment how the market will respond to increased spending by allowance recipients. To be sure, the more drastic the differences between the allowance formula actually used in the Supply Experiment and the formula whose hypothetical supply consequences are to be examined, the less direct are the inferences from experimental outcomes: more reliance must be placed on analytical modeling that uses context-free parameters drawn from both the Supply and Demand Experiments. The issues entailed in such modeling are discussed below.
INTEGRATING THE DEMAND AND SUPPLY EXPERIMENTS

In the Demand Experiment, a thin sample of low-income families living in one or more large metropolitan areas will be selected for enrollment in a housing allowance program. Subsamples of the enrollees will be given allowances on different terms, and their housing choices and budgetary decisions will be monitored for a period of several years. Because the number of allowance recipients will be small relative to the population of the housing market, increased housing expenditures by allowance recipients will not add up to significant demand pressure. No measurable supply response, in the sense of a change in the price of housing services or in the quantity supplied, can be anticipated.

The Supply Experiment works the other side of the street. Using a single allowance formula, it enrolls all eligibles in two selected metropolitan areas, creating demand pressure comparable to that anticipated from a national program. It then tracks the dynamics of supply response over a period of several years, measuring changes in the price of housing services and the quantity supplied.

By analytically combining the findings of the two experiments, we can estimate how suppliers would respond to variants of housing allowance formulas not tested in the Supply Experiment in market contexts not explored by the Demand Experiment. The analytical link between these two kinds of experiment is provided by a standard market model, in which the market price of housing services is varied until a balance is struck between the quantity of housing services demanded (which decreases with price) and the quantity supplied (which increases with price).

To perform such an analysis, it is necessary first to reduce the principal quantitative findings of both the Demand and Supply Experiments to forms which are at least quasi-independent of the particular market contexts of each experiment. In the Demand Experiment, two general types of allowance formulas will be tested: formulas that aid the recipient according to his income (housing-gap principle) and formulas that aid the recipient according to the amount of rent he pays (housing-discount principle). By careful selection of recipients to cover a range of household characteristics and incomes, and by varying the parameters of both formulas, the monitors of the Demand Experiment expect to be able to map both the income and price elasticities of
housing demand by low-income households, under a variety of special restrictions on the use of allowance payments. Because the Demand Experiment will be conducted in several housing markets, the dependence of these parameters on background conditions can also be tested.

In the Supply Experiment, we propose to estimate the price elasticity of housing supply for each of 16 sectors of the housing market, distinguished by tenure, rent or value, size of structure, and neighborhood density (urban vs. rural).* These elasticities will be estimated independently in each of two housing markets selected for their structural differences, but both subjected to comparable demand stimuli. Thus, we will have a limited but powerful test of the dependence of these parameters on market configuration.

If we are able to convince ourselves that the parameters drawn from both the Demand and Supply Experiments are indeed reasonably independent of the context in which their values were estimated, they can be used to map demand and supply functions in actual or hypothetical housing markets whose structural characteristics (numbers and types of households and their incomes, numbers and types of housing units and factor costs) can be specified. The mathematical structure of such an analysis is presented in Appendix E; it could be implemented at various levels of sophistication, depending on the amount of detailed information about the pertinent elasticities obtained from the experiments, and the amount of detailed information obtainable about the structure of the housing market to be analyzed.

Such analytical integration of the findings of the Demand and Supply Experiments does not hinge on the use of the same allowance formula in both experiments—a manifest impossibility if the Demand Experiment is to test variations in allowance formulas. The market model described in Appendix E is adaptable on the demand side to either housing-gap or housing-discount allowance formulas; the supply function formally depends on factor prices and output prices, not on the allowance-modified demand function.

* These are the dimensions of stratification selected on a priori grounds, subject to three considerations: functional significance, sampling convenience, and reproducibility from commonly available data. Doubtless, analysis of the data will lead us to combine some of these strata and to create new strata.
We do think that it would be helpful for the Supply Experiment's allowance formula to belong to a family that is represented in the Demand Experiment—preferably a family that has a high probability of eventual use as the basis for a national program. The housing-gap allowance formula fits this description. The variant of it that will be used in the Supply Experiment is scheduled for test in the Demand Experiment.

Our main reservations about the analytical integration of experimental findings do not pertain to "mixing" allowance formulas, but to the extension of supply response parameters to housing markets whose sizes and structures differ radically from those of the two experimental sites selected for the Supply Experiment. As noted earlier in this section, we are least comfortable with the issue of SMSA size, both because of untested market scale effects and because market structure varies with size, particularly with respect to the incidence of rental tenure and of multiple dwellings. While the sites under consideration for the Supply Experiment are close to national averages in these respects, they are very different from the large metropolitan areas whose housing problems preoccupy public attention. It is for this reason that we have recommended to HUD a third experimental site, consisting of a low-income neighborhood in a large metropolitan area, with enrollment in the allowance program restricted to that neighborhood. While an experiment of this type would have limited relevance to some of our research objectives (e.g., effects of the allowance program on mobility), it would enable us to gather data on supply responsiveness of the owners of deteriorated multiple dwellings in a market in which low-income renters predominate.

*Housing-discount formulas will also be tested in the Demand Experiment, as a necessary vehicle for measuring price elasticities of demand. Our analysis of recipient behavior under alternative allowance formulas leads us to hope that the housing-discount principle is not a serious contender for a "real" allowance program: we think it would be a mischievous incitement to price inflation and (in its pure form) would badly distribute the benefits of the allowance program. See Lowry, Ott, and Noland, op. cit., FN-8028-HUD.
Appendix A

A DYNAMIC MODEL OF THE PRODUCTION FUNCTION

FOR HOUSING SERVICES

Discussions of housing policy usually reflect implicit assumptions about the characteristics of the production function for housing services. Since the assumptions are not articulated, they can and often do conflict within the course of a few pages of exposition. The greatest confusion concerns the relationship among the output of housing services, maintenance expenditures, and the pattern of housing deterioration over time. This appendix attempts to sort out these issues by means of a dynamic model of the production function for housing services.

Our production function takes the following form:

$$Q_t = f(L_t, K_t, M_t, S_t)$$  \hspace{1cm} (A-1)

where $Q_t$ = the flow of housing services at time $t$;
$L_t$ = the stock of land in residential use at time $t$;
$K_t$ = the stock of residential capital improvement at time $t$;
$M_t$ = the flow of housing-maintenance inputs at time $t$; and
$S_t$ = the flow of building-service inputs at time $t$.

Output and all inputs are measured in real terms (i.e., constant-dollar values). $L_t$ and $K_t$ are valued at acquisition cost, which for $K_t$ is the cost of production.

These factors of production are distinguished because they differ with respect to the time lag between acquisition of the factor and its transformation into output. Empirically, they form a spectrum from the most durable (land) to the most fleeting (services of an elevator operator), so that the limits assigned to each category are necessarily arbitrary.

There is, however, a special relationship between two of these factors, the stock of capital and the flow of maintenance inputs: The productivity and longevity of housing capital are powerfully affected
by the level of maintenance it receives. Indeed, the distinction between what one chooses to call "capital" and what one chooses to call "maintenance" is largely a matter of the level of aggregation.

A paradigm will probably be more helpful than abstract exposition. Consider the heating system of a multiple dwelling. The original installation—furnace, fuel storage tanks, distribution ducts—is a capital item, \( K_0 \), which deteriorates over time but may be renovated by maintenance inputs, the two processes determining its current state, \( K_t \). Regular cleaning of furnace filters, oiling of blowers, etc., are maintenance activities, \( M_t \), that sustain the efficiency of the heating system and extend its useful life; occasional repairs and replacement of minor parts serve the same purposes. Eventually, it may become necessary or economical to replace a major element such as the furnace, though probably not the distribution ducts; whether this is treated as a logical extension of maintenance, \( M_t \), or as a lumpy capital input, \( LK_t \), is arbitrary.

As one aggregates over such functional systems within a building, and over groups of buildings whose replacement cycles are uncorrelated, the lumpiness of replacement items smooths out, and it is convenient to include all repairs and less-than-complete replacements in \( M_t \), along with daily or weekly chores.

At the other end of the spectrum, we wish to distinguish service inputs, \( S_t \). For our heating system, these would include fuel, whose consumption is immediately and fully reflected in the interior temperature of the building; the amount of heat provided (and fuel consumed) can be increased or decreased without substantially affecting the efficiency or longevity of the heating system.

The dynamics of our production function result from the interaction of \( K \) and \( M \) over time. We argue that for any given \( K_0 \), there exists a level of maintenance, \( M^*_t \), that is needed to maintain a steady flow of output, \( Q \); this relationship is defined by

\[
M^*_t = bK_0. \tag{A-2}
\]
We will call \( \hat{M}_c^* \) the "good-as-new" level of maintenance associated with \( \lambda_c \), the amount of capital at time \( t \). In a study of 588 project-years of data for 56 public housing projects in New York City, Rydell has shown that \( \hat{M}_c^* \) increases over time, reflecting irreversible deterioration of the capital stock as it ages.\(^*\) His data indicate the following functional form:

\[
\hat{M}_c^* = M_c^{*0}, \quad \alpha = .1.
\]  

(A-3)

Reflection on Eqs. (A-2) and (A-3) suggests a definition of real depreciation of capital due to age: If current inputs must be increasingly substituted for capital to maintain a given level of output, then the amount of capital lost, \( \hat{\Delta} K_t^* \), can be measured by the value of the additional maintenance needed, \( \hat{\Delta} M_c^* \), capitalized at the appropriate rate of interest, \( i \):

\[
\frac{\hat{\Delta} K_t^*}{\hat{\Delta} t} = - \frac{\hat{\Delta} M_c^*}{\hat{\Delta} t} = \frac{M_c^{*0} \alpha^{-1}}{i}.
\]  

(A-4)

If actual maintenance inputs, \( \hat{M}_c \), are less than \( \hat{M}_c^* \), there will be depreciation of the capital stock in addition to the depreciation that is due to age. In this case also, the value of the capital stock thus lost is measurable by the capitalized value of the expenditures on current account that would have been needed to prevent deterioration and maintain a steady flow of output. Representing cumulative depreciation due to undermaintenance as \( \hat{K}_c^{**} \) and the current amount of undermaintenance as \( \hat{M}_c^{**} \), we have

\[
\frac{\hat{\Delta} K_c^{*+}}{\hat{\Delta} t} = - \frac{\hat{M}_c^{**}}{\hat{\Delta} t} = \frac{(\hat{M}_c^* - M_c)}{\hat{\Delta} t} = \frac{M_c^{*0} \alpha^{-1} - M_c}{\hat{\Delta} t}.
\]  

(A-5)

\(^*\) C. Peter Rydell, Factors Affecting Maintenance and Operating Costs in Federal Public Housing Projects, The New York City-Rand Institute, R-634-NYC, December 1970, pp. 15-27. The official (and, Rydell judges,
Combining these two forms of depreciation, we conclude that

\[ \frac{dK_t}{dt} = -\frac{M^*_{\alpha} t^{\alpha-1}}{t} - \frac{(M^*_{\alpha} t - M^*_{\alpha})}{t} + \frac{M^*_{\alpha} t^{\alpha}}{\tau}\left(\frac{\alpha t^\alpha}{\tau - \alpha}\right). \]  

(A-6)

The expression in Eq. (A-6) involving \( \alpha \) and \( \tau \) is not immediately recognizable; but if \( \alpha \) is small (e.g., \( \alpha = 0.1 \)), the expression simplifies as \( t \) becomes large, approaching \( t^\alpha \) as a limit. Using this limiting value, we can express the depreciation rate (with \( K_t \) as a base) as

\[ \frac{dK_t}{dK_t} = \frac{M^*_{\alpha} - M^*_{\alpha} t^\alpha}{t K_t} = \frac{M^*_{\alpha}}{t K_t}. \]  

(A-7)

We can find the value of the stock of capital remaining at time \( t \) by integrating Eq. (A-6):

\[ K_t = K_0 - \frac{M^*_{\alpha}}{t} - \int_0^t \frac{(M^*_{\alpha} - M^*_{\alpha} t^\alpha) dt}{t}. \]  

(A-8)

Finally, the useful life of the original capital, \( K_0 \), ends when it becomes cheaper to replace what remains than to continue to operate it. This will occur at some point even if there is no undermaintenance, simply due to the age effect. The maximum useful life of \( K_0 \) is defined by

\[ K_0 - \frac{M^*_{\alpha} t^\alpha}{t} = 0 \quad \text{or} \quad \tau_{\text{max}} = \left[\frac{K_0}{M^*_{\alpha}}\right]^{\alpha} = \left[\frac{\alpha}{\tau}\right]^{\alpha}. \]  

(A-9)

The (actual) policy of the New York City Housing Authority is "good-as-new" maintenance; thus an increase in maintenance expenditures over the life of a given project, when adjusted for factor-price inflation, is a change in \( M^*_{\alpha} \) as defined above.
The minimum useful life of \( K \), would result from a policy of zero maintenance; from Eq. (A-8), with \( \lambda = \lambda \), we have

\[
K = -\frac{M_t^{\alpha}}{\dot{c}} - \int_0^t \frac{(M_t^{\alpha}) \dot{c} \, dt}{\dot{c}} = 0.
\]

(A-10)

Unfortunately, this equation cannot be solved analytically for \( t \); it reduces only as far as

\[
t^{\alpha} (\alpha + 1 + t) = (\alpha + 1) \frac{\dot{c}}{\dot{c}},
\]

(A-11)

which can, however, be solved by numerical approximation when values for the other variables and for \( \alpha \) and \( \dot{c} \) are known.

Our model includes two technological parameters. One is \( \beta \), which relates the amount of maintenance needed to offset current depreciation to the original value of the capital stock. The other is \( \alpha \), which relates the growth of good-as-new maintenance inputs to the passage of time. The second of these parameters has been evaluated \((\alpha = .1)\) by Rydell, op. cit., in a context that gives reasonable grounds for generalization. With less assurance, we can also estimate the value of \( \beta \).

The difficulty is primarily that expense data are insufficiently detailed to permit us to separate thoroughly outlays which effect the capital stock, \( M_t \), from those used for building services, \( S_t \). Rydell's data show the following expense distribution for his standard case, a 21-year-old project in 1968 with 1,000 units, 10 buildings, and 800 square feet per unit.*

<table>

* Rydell, op. cit., pp. 54-55.
Utilities and management expenses revealed no significant tendency to increase with project age and may be presumed to be components of $S_t$. Service expenses (which include janitorial, security, grounds, and plumbing services; general supervision of the maintenance and service staff; and contributions to the pension fund) show a small tendency to increase as projects age; they are manifestly a mixture of $M_t$ and $E_t$. Repair and painting expenses are the most powerfully influenced by project age, obviously belonging in $M_t$.

The combined total of repair and painting expenses for the standard case, $206$, is thus probably on the low side of $M_t^*$; it will serve at least as a rough estimate for the standard case, $t = 21$. We can calculate from Eq. (A-3) that

$$M_t^* = \frac{M_t^*}{21} = \frac{206}{2.256} = 81.32,$$

(A-12)

which is about 1 percent of construction costs per unit ($14,300 in 1968 dollars).*

Another New York City data base leads to roughly the same conclusions. Audited expense data on 311 rent-controlled (pre-1947) multiple dwellings, free of housing-code violations, yield an average annual expenditure (in 1965-1967 dollars) of $135 per unit for maintenance, repairs, replacements, and improvements. ** The average building in the sample was 38 years of age, consisted of 56 units with an average of 3.55 rooms, and had an estimated market value of $7,650 per unit. Its violation-free status suggests that current maintenance, at least, was adequate. If we assume, precariously, that the building has a history of adequate maintenance,

$$K_t = K_0 - \frac{M_t^*}{t} \quad \text{or} \quad K_t = 87,860 + \frac{81.32}{t}. \quad \text{(A-13)}$$

---

* Rydell, op. cit., p. 57.
**Karen M. Eisenstadt, Factors Affecting Maintenance and Operating Costs in Private Rental Housing, The New York City-Rand Institute, R-1055-NYC, August 1972, Table 8.
Capitalizing at \( i = .10 \), we obtain \( \hat{K}_o = \$9,000 \); and repeating the calculation of Eq. (A-12), we have

\[
\frac{M^*_o}{\hat{K}_o} = \frac{\frac{\hat{K}_o}{i}}{\hat{K}_o} = \frac{\$9,000}{.10} = \$90,000,
\]

which is about 1 percent of \( \hat{K}_o \).

To summarize, then, we have estimates of our technological parameters,

\[
a = .1 \quad \text{and} \quad b = \frac{K^*_o}{\hat{K}_o} = .02.
\]

Applying these parameters to Eqs. (A-9) and (A-11), and assuming an interest rate of 10 percent, we can solve for the maximum and minimum useful lives of residential capital, \( \hat{K}_o \). It turns out that

\[
\tau_{\text{max}} = 10^{10} \text{ years},
\]

and

\[
\tau_{\text{min}} = 8 \text{ years}.
\]

In other words, a well-maintained building will last indefinitely, and a poorly maintained building can be run into the ground in only a few years.

These formulations of the maximum and minimum lives of residential capital assume that \( M^*_o \) is a function only of \( \hat{K}_o \) and \( \tau \). It could alternatively be argued that as the capital stock diminishes due to under-maintenance, the amount of maintenance needed to prevent further depreciation (except that part due to the passage of time) also decreases. Thus, if \( M^*_o \) is defined as the "hold-the-line" level of maintenance, a function of \( \hat{K}_o \) and \( \tau \), the rate of capital loss for a regime of under-maintenance would be less than the calculations above indicate.

Thus, if we replace
The results given in Eq. (A-15) are an approximate solution of Eq. (A-6), using the revised concept of $E$. The exact solution leads to a more complicated exponential term in the equation but does not give appreciably different numerical results.
to the loss of most of a building's real value in a relatively short time.

Of course, residential-property owners seldom follow either a policy of good-as-new maintenance or a policy of zero maintenance. The policies they do choose, we think, reflect their expectations about the demand for output. Faced with declining demand in the foreseeable future, they can adjust output by decreasing maintenance outlays, losing capital but saving on current account.

Appendix B

ACCOUNTING FOR SUPPLY RESPONSES

Among the four major research objectives of the Supply Experiment, we expect that measuring supply responses to the experimental allowance program will be the most difficult, both in terms of data collection and in terms of analysis. To serve this objective, we propose a program of field surveys to gather longitudinal data on a sample of residential properties in each experimental site.

In order to obtain systematic evidence of additions to and deletions from the stock of housing, as well as changes in the characteristics of the existing inventory, the sample has three components:

1. A stratified random sample of tax parcels in residential use at the time of the baseline survey, prior to the commencement of the allowance program; this sample is drawn from the entire area of the experimental site.

2. A random sample of tax parcels not in residential use, but which may be converted to residential use during the experiment; this sample will be selected at baseline and is confined to the urbanized portion of the experimental site.

3. Outside the urbanized portion of the site, a sample of residential building permits that will be drawn each year after baseline, to capture evidence of additions to the housing supply in territory where they are too spotty to be efficiently sampled by the method described under Item 2, above.

Each element of the combined sample will be surveyed annually for that portion of the experimental period during which it is in residential use. The surveys will gather data on the physical characteristics of the residential structure, on the income and expenses of its operation, and on the characteristics of its owner and tenants. We expect to observe by these means a representative sample of all changes in the supply of housing services that occur during the experiment.
Presumably, the major cause of such changes will be an increase in effective demand for housing services by low-income households, generated by the allowance program. General public knowledge of the program, combined with attempts by allowance-eligible households to obtain certifiable housing units and thus qualify for allowance payments, should prompt various responses from the owners of residential property in those sectors of the market in which allowance recipients are active. Our task is to measure these responses, not merely for those housing units actually occupied by allowance recipients, but throughout the affected sectors of the market.

We emphasize that supply responses to the allowance program will not be confined to housing units actually occupied by allowance recipients. Since the allowance is attached to the eligible household rather than to any particular housing unit, owners of deteriorating residential property may seek to attract recipients by speculative housing improvements, or they may lose tenants by failure to make such improvements. Owners of well-maintained housing, on the other hand, may be able to raise rents without making improvements because of increased demand from allowance-eligible households for such units. In fact, the suppliers of housing services will not always be able to distinguish the allowance program as the source of market signals that influence their production and pricing policies, perceiving only that the demand for some kinds of housing has increased and the demand for other kinds of housing has decreased.

Changes in housing demand that occur during the experiment will be reflected in changes in housing expenditures, readily measurable for our sample of residential structures. By definition, a change in housing expenditures is accountable on the supply side to some combination of (a) changes in the flow of housing services produced and (b) changes in the price per unit of these housing services. To evaluate the results of the experimental allowance program, both for allowance recipients and others, we must distinguish these two aspects of supply response.

In Sec. VI, we argued that since changes in the flow of housing services cannot be measured directly, the next best alternative is to
measure changes in the flow of factors used in the production of housing services. This appendix provides a rigorous (i.e., algebraic) explanation of the method by which we propose to measure these input changes and shows how we can then estimate the magnitude of concurrent price changes, distinguished according to their causes and their relevance to the interests of the experiment. The empirical procedures required for each step are indicated but not detailed.

For the reader's convenience, the notation used in this appendix is summarized on the following page.

MEASURING CHANGES IN FACTOR INPUTS

For each residential structure in our sample, we propose to measure the flow of factor inputs for the year preceding the commencement of the allowance program, and to measure changes in this flow for each succeeding year. Our primary concern is to devise a measurement scheme that is sensitive to aggregate changes in factor inputs for sectors of the housing market that are likely to be substantially affected by the allowance program, changes that can be related to corresponding changes in housing expenditures within those same market sectors. The scheme will allow tracking of the fates of individual structures, and analysis of these fates may cast additional valuable light on the processes of supply response; but our emphasis is on aggregate supply response to market signals rather than on individual buildings or transactions between individual landlords and individual tenants.

During the base year, we propose an inventory and appraisal of all residential properties included in the sample, with land and capital improvements appraised separately. We also propose a field survey of property owners, designed to yield a full accounting of rental revenues received, maintenance and operating expenses during the base year, and real-estate taxes paid. Although information about mortgage financing will be gathered at this time, it is not used in the measurements described below.

\[ v'_c = f'_c w'_c = c \left[ v'_c + v'_w \right] + v'_a + v'_o \]  

(E-1)
NOTATION

Principal Variables

V = market value of factor inputs or housing-service outputs, measured at base-year prices
P = price per unit of factor input or housing-service output
Q = number of units of factor inputs or housing-service outputs
Z = market value of land or existing capital improvements added to or removed from residential use, measured at base-year prices
W = quantity weights used in the construction of factor-price indexes
R = rental revenue received by the producers of housing services
A = producers’ markup, the ratio of sales price to cost of production

Subscripts on Principal Variables

f = generalized factors used in the production of housing services
   (a mixture of l, k, c, m, and s)
l = residential land
k = capital improvements in place
c = current capital improvements (new construction or alterations)
m = current inputs for building maintenance and repairs
s = current inputs for building services and operations
h = housing services
t = real-estate taxes
g = h + t

Parameters

i = market rate of interest on residential mortgages
r = real rate of depreciation of capital improvements

Dating the Variables

To simplify notation, variables have not been explicitly dated. Instead, base-year values are written without superscripts (e.g., \( F_m \)); test-year values are distinguished by prime superscripts (e.g., \( F_m' \)); and differences between test-year and base-year values are indicated by a preceding delta (e.g., \( F_m' - F_m = \delta F_m \)).
In Eq. (B-1), we sum the market values of factors used in the production of housing services during the base year. The first term on the right-hand side measures the opportunity cost of residential land and capital in use during the base year, assuming a midyear appraisal.\(^*\) Opportunity cost is defined as appraised value multiplied by the market rate of interest on residential mortgages; it is the amount that the suppliers of housing must pay annually for the use of this land and capital.\(^**\)

The remaining two terms on the right-hand side of Eq. (B-1) measure outlays during the base year for maintenance and repairs, \(V_m\), and building services, \(V_b\). They are distinguished for reasons that will become apparent below.

The sum of these three terms, \(V_f\), is the base against which we wish to measure changes in the flow of factor inputs during the years of the experiment. Insofar as possible, we propose to measure these changes by event recording. By so doing, we are less likely to overlook small but significant changes, and we avoid the inconsistencies that would result from direct reappraisal of capital assets under changed demand conditions.

\[
V'_f = P \sum_{f} = \left[ V'_L + V'_K \right] + V'_m + V'_b .
\]

Equation (B-2) sums the values, in base-year dollars, of factor inputs during the first test year. Although Eq. (B-2) is parallel in form to Eq. (B-1), the measuring procedures are more complicated. The value of each factor input must be either measured in or adjusted to base-year prices so that \(V'_f\) is comparable to \(V_f\) in "real" terms. Item-by-item, the procedures are as follows:

\[
V'_L = V'_L + Z'_L .
\]

\[
V'_K = (1 - \rho)(V'_K + Z'_K) + v' .
\]

\(^*\) This assumption simplifies the algebra, but the method is adaptable to any schedule of fieldwork.

\(^**\) This point is discussed further at the end of this section.
Residential land and capital improvements are accounted for in the middle of the test year. In Eq. (B-3), \( Z_1 \) represents parcels of land added to (+) or withdrawn from (-) active residential use since the base-year inventory, valued at their base-year appraisals. In Eq. (B-4), \( Z_k \) is similar, representing existing structural improvements whose use has shifted from residential to nonresidential, or the reverse. Thus if a residential building was boarded up, destroyed by fire, or converted to offices, its base-year appraised value would be deducted from \( V_{k-1} \), and the value of its site would be deducted from \( V_{z-1} \). (Note, however, that a vacant or partially vacant residential building, if available for rent, remains in \( V_{k} \) and \( V_{z} \).) The last term of Eq. (B-4) records the value of residential construction and alterations completed subsequent to the base-year inventory.

Data on these occurrences could be obtained from municipal permits, required for most of the events here described. However, we also plan annual field inspection and interviews with owners and tenants to verify the completeness and accuracy of permit data.

In Eq. (B-4), the value of capital improvements, net of conversions, is adjusted for depreciation since the base-year appraisal. In Appendix A, we related the rate of capital depreciation to the age of the capital and the level of current maintenance. For mature housing, we concluded there (Eq. (A-7)) that the relationship could be approximated well by

\[
\frac{dV_{z}}{dt} = -\frac{\beta}{V_{z}} \cdot V_{z}^4
\]

Changing to the notation used in the present appendix, and shifting from continuous time to one-year intervals, we can define the base-year rate of capital depreciation as a positive fraction, \( r \):

\[
r = \frac{V_{z}^4 - V_{z}}{V_{z}^2}
\]
Here, $V_m^*$ is the outlay required for "good-as-new" maintenance of the base-year capital stock, $V_m$. The rate of depreciation of $V_m$ thus depends on the difference between $V_m^*$ and actual maintenance outlays, $V_m$. The cost of good-as-new maintenance amounts to about 1 percent of $V_m$ for mature buildings; it can be estimated more precisely from that part of the expense-survey data that pertains to buildings which are manifestly in good condition.

\[
\frac{Y_m'}{Y_m} = \frac{P_m}{P_m'} = \frac{P_m P_m^*}{P_m^* P_m'}.
\]

\[
\frac{Y_s'}{Y_s} = \frac{P_s}{P_s'} = \frac{P_s P_s^*}{P_s^* P_s'}.
\]

The remaining terms of Eq. (B-2) are elaborated in Eqs. (B-6) and (B-7), above. Each year during the course of the experiment, the field survey of building revenues and expenses must be repeated. Maintenance and service outlays for the test years are taken from these surveys and deflated to base-year prices by appropriate price indexes (see Appendix D).

As noted in Appendix A, ordinary real-estate accounting practices do not always neatly distinguish outlays for maintenance and repairs, $V_m$, from outlays for building services, $V_s$. However, the distinction is pertinent only to our estimate of $r$, which is derived by differencing $V_m^*$ and $V_m$. So long as the accounting is consistent over time, the classification of marginal items as $V_m$ or $V_s$ will have little effect on $(V_m^* - V_m)$.

This completes our expansion of Eq. (B-2), which measures the value of factor inputs during the first test year, but in base-year prices. The procedures for subsequent years are analogous. By differencing Eqs. (B-1) and (B-2), we obtain the change in factor inputs between the base and test years:

---

* See Appendix A.
\[ \Delta V_f = V_f' - V_f = \frac{E_f \Delta \hat{a}_f}{\hat{a}_f} \cdot \]  

This difference may be conveniently generalized by expressing it as a ratio to the base-year value:

\[ \frac{\Delta V_f}{V_f} = \frac{E_f \Delta \hat{a}_f}{\hat{a}_f} = \frac{\Delta \hat{a}_f}{\hat{a}_f}. \]  

Thus, without ever having to specify exactly in what units of account we measure factor inputs, we have derived the relative change in real factor inputs for the first year of the experiment. We can thus determine by what percentage total factor inputs have increased or decreased as a result of the allowance program and/or concurrent background events.

Three features of this accounting for factor inputs should be emphasized because they bear directly on the interpretation of the results.

First, the contribution of residential land and structural improvements is measured by their opportunity cost: the market rate of interest on residential mortgages multiplied by the base-year appraised value of residential real estate. This opportunity cost is analogous to explicit payments for other factor inputs in the sense that the market rate of interest is what an investor must pay for the use of residential land and capital improvements. Of course, the actual rates of interest on existing mortgage debt may be higher or lower than the current rate, depending on money-market conditions at the time the debt was incurred. If so, building owners will have capital gains or losses that would be realized if they sold their properties on the current market. We are not concerned with that history, only with future events; so we need not take into account the terms of existing mortgage instruments or the fraction of appraised value that is covered by outstanding mortgage debt. These considerations are irrelevant to our attempt to measure "real" factor inputs.

Second, it has been suggested to us that Eq. (B-1) should contain an additional term, \( rV_x \), measuring capital consumption during the base year and treating it as a factor input:
Instead, we treat depreciation of capital improvements only as disinvestment which reduces opportunity cost in subsequent years (see Eq. (B-2)).

The accounting for capital consumption suggested in Eq. (B-10) has a surface plausibility, but it confuses the measurement of factor inputs with cash-flow accounting. The easiest way to demonstrate the illogic of treating \( r^* \) as a current factor input is to explore the implications of this method of accounting. As we have shown in Appendix A, the rate of depreciation is a function of the age of capital and the level of its maintenance; these propositions are reflected in Eq. (B-5), repeated below in slightly different form:

\[
r^*_{K} = \frac{V^*_m - V_m}{i}.
\]

From this equation, we can see that there is a tradeoff between \( V^*_m \) and \( r^*_{K} \), which is independent of other terms in Eq. (B-10). If \( V^*_m = V_m \), then \( r^*_{K} = 0 \); at the other extreme, if \( V^*_m = 0 \), \( r^*_{K} = \frac{V^*_m}{i} \). We can simplify by combining \( V_m \) and \( r^*_{K} \) into a single expression:

\[
r^*_{K} + V_m = \frac{V^*_m - V_m}{i} + V_m = \frac{V^*_m - (1 - i)V_m}{i}.
\]

Substituting this last expression into Eq. (B-10) shows that under such an accounting system, an increase in current maintenance outlays, \( V_m \), would be counted as a decrease in total factor inputs—a nonsensical result. Capital consumption is not a real factor input on such an account.

The final point to be made about our accounting for changes over time in the flow of factor inputs is that the choice and staging of time intervals is necessarily arbitrary. In our scheme, stock accounts (land and capital improvements) are compiled at midyear; flow accounts (maintenance and service inputs, depreciation allowances) are compiled.
at year-ends. This particular choice simplifies the algebra and poses no special difficulties in scheduling field work; but the accounting could be adapted to any reasonable alternative that provided more or less concurrent data on capital and current accounts.

RELATING FACTOR INPUTS TO HOUSING-SERVICE OUTPUTS

In Sec. II of this report, we argue that the output of housing services cannot be rigorously defined or cardinaly measured in physical units. If this is so, the relationship between factor inputs and housing-service outputs is necessarily ambiguous. Given that we can measure changes in "real" factor inputs, can we say anything specific about the resulting changes in the flow of housing services?

As a point of departure, we may take the conventional model of the firm in long-run equilibrium. Given the demand for output and the prices of the several factors of production, a firm which has achieved equilibrium will be using the most efficient combination of factors for the desired level of output. If such a firm then attempts to change the level of output in response to altered demand conditions, there will be a period of time in which the factor mix is less than optimal for the new level of output because not all factors are instantaneously variable. Furthermore, the new equilibrium position, when achieved, may be either more or less efficient than the old one.

If, as we expect, the allowance program primarily affects market sectors in which deteriorating housing is the norm, this implies that most producers of housing services in these sectors are not in equilibrium during the base year, but have been systematically reducing their levels of output from those for which their buildings were initially designed. They will have accomplished this by reducing those factor inputs that are easy to vary—building services and maintenance outlays—and by abstaining from capital replacement as the building deteriorates.

If, during the base year, our producers are operating with a suboptimal factor mix in their attempt to adapt to a lower level of output, an increase in the demand for output will enable them to raise their sights, moving toward the optimal factor mix of the original design.
In this phase of upward readjustment, the efficiency of the production process should increase.

With a large increase in demand, producers might seek to increase output above the level that is optimal for the existing stock of capital. To do so, they could in the short run add building services, presumably subject to declining marginal product. In this phase of upward readjustment, the efficiency of the production process would decrease. Given more time, the producers could add capital improvements as well as maintenance and service inputs, achieving something like a proportional increase in all factors. As compared with the short-run readjustment, the efficiency of the production process would increase as a more nearly optimal factor mix was achieved.

If these three phases of readjustment to increased demand occur strictly in sequence, they imply first declining, then rising, then declining average costs. But they need not occur in strict sequence; certainly the first two could be telescoped in time, given a sharp increase in demand at the beginning of the experiment. Without knowing a good deal more than we do about the technology of housing deterioration and repair, we cannot judge which effect would dominate at any particular time.

It is possible that the experiment itself will enable us to learn something about the relationship between real input changes and real output changes. In Appendix C, we show how regression techniques might be used to estimate the parameter \( \gamma \) in a production function of the form \( q_h = (\zeta_{z_0})^{\gamma} \). In the meantime, however, our best assumption seems to be

\[
\frac{\Delta \zeta_h}{\zeta_h} = \frac{\Delta \zeta_f}{\zeta_f}.
\]  

(B-13)

In other words, we provisionally propose that the flow of housing services changes proportionally to the flow of factor inputs. This assumption is used below in estimating changes in the market price of housing services during the course of the housing allowance experiment.
MEASURING CHANGES IN THE PRICE OF HOUSING SERVICES

In the first section of this appendix, we presented a method for estimating changes in the flow of factor inputs between the base year and each subsequent year of the housing allowance experiment. Given those estimates, and the identity postulated in Eq. (B-13) above, we can also estimate the concurrent change in the price of housing services.

\[ \bar{R}_h = \bar{R}_c - \bar{R}_t = \bar{P}_h \bar{Q}_h \cdot \]  \hspace{1cm} (B-14)

Gross rental revenue, \( \bar{R}_c \), can be divided into a payment for housing services, \( \bar{R}_h \), and a tax, \( \bar{R}_t \), that the landlord must deduct from his gross revenue. While the tax supports some services that the consumer associates with housing, the amount of the tax bears only a tenuous relationship to the amount of service delivered; the supplier cannot purchase more or less public services by offering to pay more or less taxes.

Also, the payment for housing services whose production is under landlord control, \( \bar{R}_h \), can be defined as \( \bar{P}_h \bar{Q}_h \). We propose to observe both rental revenue and real-estate tax payments in the base year and the test year; these data enable us to estimate \( \bar{P}_h \) and \( \bar{Q}_h \) as residuals of rental revenue after deduction of taxes. Differentiating them gives us \( \Delta \bar{R}_h \), the change in aggregate payment for housing services, which we decompose as follows:

\[ \Delta \bar{R}_h = \Delta \bar{R}_c - \Delta \bar{R}_t = \Delta \bar{P}_h \bar{Q}_h + \Delta \bar{P}_h \Delta \bar{Q}_h + \bar{P}_h \Delta \bar{Q}_h \cdot \]  \hspace{1cm} (B-15)

Dividing Eq. (B-15) by Eq. (B-14), we obtain

\[ \frac{\Delta \bar{P}_h}{\bar{P}_h} = \frac{\Delta \bar{P}_h \bar{Q}_h}{\bar{P}_h \bar{Q}_h} + \frac{\Delta \bar{P}_h \Delta \bar{Q}_h}{\bar{P}_h \Delta \bar{Q}_h} + \frac{\bar{P}_h \Delta \bar{Q}_h}{\bar{P}_h \Delta \bar{Q}_h} = \bar{P}_h \left[ \frac{\Delta \bar{Q}_h}{\bar{Q}_h} + \frac{\Delta \bar{Q}_h}{\bar{Q}_h} \right] + \frac{\Delta \bar{Q}_h}{\bar{Q}_h} \cdot \]  \hspace{1cm} (B-16)

Observing values for \( \Delta \bar{Q}_h \) and \( \bar{Q}_h \), and using the identity postulated in Eq. (B-13), we can solve for the relative increase in the price of housing
services between the base and test years:

\[
\frac{\Delta F_R}{P_R} = \left( \frac{\Delta V_R}{V_R} - \frac{\Delta W_R}{W_R} \right) \left( 1 + \frac{\Delta Q_R}{Q_R} \right)^{-1}.
\]  

(B-17)

We have noted that this estimate depends on Eq. (B-13), which asserts that the percentage change in the output of housing services is identical with the percentage change in factor inputs. If, in fact, the attempt to increase output encountered diminishing returns, i.e., if

\[
\frac{\Delta Q_R}{Q_R} < \frac{\Delta W_R}{W_R},
\]

then our accounting method would lead us to underestimate \(\Delta F_R/F_R\). If increasing returns were encountered, we would overestimate this relative change in the price of housing services. Appendix C proposes a supplementary analysis that would detect these conditions. Such errors, however, would have no effect on the further accounting procedures presented below, or on the interpretation of their results.

**ACCOUNTING FOR PRICE CHANGES**

The price changes measured by Eq. (B-17) could come from any of several sources. They may reflect changes in the prices of external factors of production purchased currently by the suppliers of housing services (\(\Delta F_s\), \(\Delta F_g\), or \(\Delta F_e\)); changes in the opportunity cost of capital as indicated by the market rate of interest (\(\Delta i\)); or changes in the owners' profits, net of the opportunity cost of their stock of capital (\(\Delta F_e\)). For the housing allowance experiment, it is important to distinguish among these several price changes because they have different implications for the costs of a national program. The total price change can be decomposed as follows:

\[
\frac{\Delta P_f}{P_f} = \frac{\Delta F_s}{F_s} \left( \frac{V_f}{V_f} \right) + \frac{\Delta F_g}{F_g} \left( \frac{V_g}{V_f} \right) + \frac{\Delta F_e}{F_e} \left( \frac{V_e}{V_f} \right).
\]  

(B-18)
Each term on the right-hand side of Eq. (B-18) accounts for a factor-price change (relative to the base-year factor price), weighted by that factor's share in total factor costs (current quantities in base-year prices). The weights, segregated by brackets, are all available from previous calculations; excluding the second term, the numerators of the weights sum to the common denominator, \( v_j' \).

The second term is needed to distinguish the effects of rising construction costs for capital improvements from the effects of rising interest rates. The reader will recall from Eq. (B-4) that capital improvements enter \( v_j' \) at the end of the year in which they occur, valued in base-year rather than current prices. Consequently, a separate term is needed to capture changes in construction costs. Actually, complete accounting would require a third term of the form

\[
\frac{\Delta C}{t} = \frac{\Delta \Delta C}{\Delta \Delta P} \left( \frac{t - (v_j' \Delta C)}{\Delta \Delta P} \right),
\]

which we here neglect on the grounds that it would be very small. For similar reasons, we neglect the minor disparity in the weighting scheme noted above; it could, however, be remedied by rescaling the first two bracketed weights.

Once factor-price changes are accounted for, there remains a possible residual, the change in owners' rate of profit. It is convenient to measure the rate of profit as a markup on the cost of production; e.g., for the base year,

\[
\tau = \frac{F_h}{P} = \frac{F_h}{F'},
\]

(B-19)

With \( \tau \) so defined, we can write

\[
\frac{\Delta F_h}{F_h} = \frac{\Delta F}{F'} + \frac{\Delta \eta}{P} + \frac{\Delta F \Delta \tau}{F'},
\]

(B-26)
The last term will be small and can be neglected. We can then estimate the change in markup rate by subtraction, i.e.,

$$\frac{\Delta \pi}{\pi} = \frac{\Delta F}{F_h} - \frac{\Delta F}{F_f}. \quad (B-21)$$

If \(\Delta \pi / \pi\) is positive, this indicates that part of the measured increase in the price of housing services is attributable to an increase in the producers' markup on factor inputs. If it is negative, the producers are absorbing part of the inflation in factor prices. Since the change in the markup rate is observed ex post, we cannot tell for sure whether the outcome reflects a planned change in the markup rate or simply a miscalculation of costs or of demand for output. But if the change is large, we can reasonably infer that it was planned.

If the base-year situation were one in which the production of housing services was decreasing (i.e., owners were reducing services and disinvesting through undermaintenance), this is prima facie evidence that \(\pi\) was then too low to compensate for entrepreneurial risk; it might even have been less than unity. In this case, we would expect a threshold effect in supply responsiveness: Not until the anticipated value of \(\pi\) exceeded some minimum value, at least greater than unity, would owners decide to increase their production of housing services. Thus, for housing that has been allowed to deteriorate, we would not expect to find an increase in output without an accompanying increase in the markup rate. The question of interest is, How large will this increase be?

**DECOMPOSING CHANGES IN RENTAL REVENUE**

We are now in a position to determine how the increased rental revenue resulting from our housing allowance experiment divides into payments for increased housing services, for increased real-estate taxes, for factor-price changes, and for owners' profits. We begin with the observed change in gross rental revenue, obtained by differencing reported rent receipts in the base and test years, which we
divide into three components:

\[ \Delta R_G = \Delta R_C + \Delta V_f + \Delta P_{H} \Delta V_f^t. \]  

(B-22)

The first term on the right-hand side, \( \Delta R_C \), is the change in real-estate taxes, obtained directly from fieldwork (by differencing reported real-estate tax liabilities in the base and test years). The value of the second term, \( \Delta V_f \), was calculated in Eq. (B-8); it measures the increase in real factor inputs over the same interval. The last term, \( \Delta P_{H} \Delta V_f^t \), can then be derived as a residual; it is the portion of the rent increase absorbed by the various price increases that occurred between the base and test years.

This last term can be further decomposed with the aid of Eqs. (B-18) and (B-21). Simplifying the notation of Eq. (B-18) by defining the bracketed factor-price weights as \( \tilde{W}_c, \tilde{W}_a, \tilde{W}_m, \) and \( \tilde{W}_s \), respectively, and substituting for \( \Delta P_f / \tilde{P}_f \) from Eq. (B-21), we have

\[ \frac{\Delta P_{H}}{\tilde{P}_{H}} = \frac{\Delta \tilde{W}_c}{\tilde{P}_c} + \frac{\Delta \tilde{W}_a}{\tilde{P}_a} + \frac{\Delta \tilde{W}_m}{\tilde{P}_m} + \frac{\Delta \tilde{W}_s}{\tilde{P}_s} + \frac{\Delta \tilde{V}}{\tilde{V}}. \]  

(B-23)

This equation can be normalized, multiplying through by \( \tilde{P}_{H} / \Delta P_{H} \), so that each term on the right is expressed as a fraction of the left-hand term. The normalized version can then be used to decompose the last term of Eq. (B-22):

\[ \Delta P_{H} \Delta V_f^t = \Delta P_{H} \tilde{P}_{H} \left[ \frac{\Delta \tilde{W}_c}{\tilde{P}_c} + \frac{\Delta \tilde{W}_a}{\tilde{P}_a} + \frac{\Delta \tilde{W}_m}{\tilde{P}_m} + \frac{\Delta \tilde{W}_s}{\tilde{P}_s} + \frac{\Delta \tilde{V}}{\tilde{V}} \right]. \]  

(B-24)

The multiplicative term preceding the bracket reduces to \( \tilde{P}_{H} \Delta V_f^t = V_f^t \). Distributing \( V_f^t \), and substituting into Eq. (B-22), we have the complete decomposition of the increase in rental revenue:

\[ \Delta R_G = \Delta R_C + \Delta V_f + \frac{\Delta \tilde{W}_c}{\tilde{P}_c} \tilde{V}_c + \frac{\Delta \tilde{W}_a}{\tilde{P}_a} \tilde{V}_a + \frac{\Delta \tilde{W}_m}{\tilde{P}_m} \tilde{V}_m + \frac{\Delta \tilde{W}_s}{\tilde{P}_s} \tilde{V}_s + \frac{\Delta \tilde{V}}{\tilde{V}}. \]  

(B-25)
The terms on the right-hand side have been labeled for ease of reference. If Eq. (B-25) is normalized by multiplying through by \((\Delta\overline{X}_g)\), they may then be interpreted as percentages of the total increase in rental revenues (expenditures) attributable to changes in

a. Real-estate taxes;
b. The quantity of factor inputs;
c. The market rate of interest;
d. Prices of capital-improvement inputs;
e. Prices of maintenance and repair inputs;
f. Prices of building-service inputs; and
g. Producers' markup on factor costs.

Thus, the housing allowance experiment can be designed to reveal how the benefits of an added dollar of housing expenditures are divided up by market processes.

The direct beneficiary of Share (a) is the municipal fisc; in a national program of housing allowances, the resulting increase in real-estate taxes would be considerable—on the order of 15 to 25 percent of the increase in housing expenditures—unless effective tax rates on market value were lowered.

Share (b) is the only direct benefit that accrues to tenants. Strictly speaking, it is the increase in the quantity of resources used to produce housing services; whether the physical output of housing services increases commensurately is, we have argued, a metaphysical question.

Share (c) is received by the owners of residential property but would be passed on by them to suppliers of mortgage funds when existing mortgages were refinanced or new indebtedness was incurred. Under our experimental conditions, changes in the market rate of interest would be determined mostly by events in a much broader capital market; under a national program of housing allowances, it is possible that increased demand for mortgage funds would drive up the market interest rate.
Shares (d), (e), and (f), in the experimental context, reflect inflationary forces in the economy in general. Depending on the scale of the experiment, they might also include inflation directly attributable to the housing allowance payments; the other side of this effect, however, would be an increase in consumer incomes which should in some degree lessen the need for housing allowances.

Share (g) is also received by the owners of residential property. It is their compensation for undertaking to increase the output of housing services. We expect this share to rise sharply at the beginning of the experiment, then gradually decline. In a demand-stabilized market, the producers' markup rate, \( X \), should eventually settle at a level adequate to compensate for normal risks.

Overall, the responsiveness of housing supply to an increase in effective demand can be judged by the magnitude of Share (b), i.e., by the percentage of the incremental expenditure for housing that went for real increments of output. A more discriminating judgment, however, would certainly net out fiscal recapture through real-estate taxes and background inflation, leaving only program-caused inflation in factor prices and changes in owners' profits as relevant inefficiencies.

Appendix B describes the sources of data and the procedures we plan to use to construct factor-price indexes for each experimental site. Most of the data are collected by existing statistical systems, not only for the candidate experimental sites, but for a number of other metropolitan areas within the same geographic region. For each factor used to produce housing services, the average price change within the larger region is a measure of background inflation, unrelated to the market disturbances created by the experimental allowance program.

Thus, netting out nonlocal background inflation in factor prices enables us to focus on site-specific inflation of factor prices as a possibly adverse effect of the allowance program. In principle, site-specific inflation, if any, will reflect some combination of (1) allowance-induced changes in housing demand; (2) changes in housing demand that are independent of the allowance program; (3) changes in demand within other sectors of the local economy that use the same factors of production; and (4) possibly even local changes in supply
conditions two or more steps removed from the production of housing services.

In fact, we do not expect either the allowance program or these other events to have a significant influence on local factor prices; we expect that the needs of policy analysis will be quite adequately served by a fortiori argument, i.e., that the total observed site-specific inflation is the maximum that could have been caused by the allowance program. However, in the event that the amount of site-specific factor-price inflation is large, we see at least limited possibilities for further analysis to distinguish the direct responsibility of the allowance program. The general approach is described in Appendix D.
Appendix C

ESTIMATING PARAMETERS OF THE PRODUCTION FUNCTION
FOR HOUSING SERVICES

In Appendix B, we proposed a method for measuring changes in the price of a unit of housing services that entails a strong assumption about the characteristics of the production function-i.e., that the flow of housing services changes proportionally with the flow of factor inputs, or

\[
\frac{\Delta \tilde{q}_n}{\tilde{w}_n} = \frac{\Delta \tilde{w}_f}{\tilde{w}_f} \quad \text{(C-1)}
\]

An assumption was necessary because we do not think that the flow of housing services can be rigorously defined or directly measured in physical units; the particular assumption of constant returns to scale was chosen because it seems likely to be approximately correct for the sectors of the housing market with which we are principally concerned. *

It is possible, though not certain, that the experiment itself will enable us to estimate the relationship between real input changes and real output changes in the range of policy interest. The estimating procedure is based on three simple ideas: First, if for some buildings at our experimental site we observe no change in the quantity of factor inputs, we can reasonably conclude that the quantity of output has not changed; for these buildings, the relative change in the price per unit of output would then be equal to the relative

*See Appendix B, "Relating Factor Inputs to Housing Service Outputs." In any event, the most important results of that analysis, the decomposition of changes in rental revenue into producers' costs and profits, are independent of this assumption.
change in rental revenue, or

\[
\frac{\Delta \bar{P}}{\bar{P}} = \frac{\Delta \bar{x}}{\bar{x}} \quad \text{if} \quad \frac{\Delta \bar{P}}{\bar{P}} = 0.
\]  

(C-2)

Second, if the price change thus measured applies equally to buildings whose factor inputs were observed to have changed, we could use this information to estimate the relative change in output for those buildings; from the identity \( \bar{P} = P \omega \), we can derive

\[
\frac{\Delta \bar{Q}}{\bar{Q}} = \left( \frac{\Delta \bar{x}}{\bar{x}} - \frac{\Delta \bar{P}}{\bar{P}} \right) \left( 1 + \frac{\Delta \bar{P}}{\bar{P}} \right)^{-1}.
\]  

(C-3)

Finally, we could compare these estimates of output changes with measured changes in factor inputs for each building to estimate the ratio \( \gamma \) of output changes to input changes:

\[
\frac{\Delta \bar{Q}}{\bar{Q}} = \frac{\Delta \bar{x}}{\bar{x}}.
\]  

(C-4)

This estimate could then replace our assumption in Appendix B of constant returns to scale \( \gamma = 1 \).

Since it is unlikely that there will be many buildings whose measured quantities of inputs will remain constant during the experiment, the method of estimating the relationship between real input changes and real output changes cannot be quite as simple as the paradigm above suggests. However, we can nonetheless use buildings with only small changes in factor inputs to inform us about price changes, and buildings with large changes in inputs to inform us about the characteristics of the production function. Regression techniques enable us to do both steps simultaneously and obviate the need for a set of buildings for which only price changes occur.

Below, we sketch a procedure for estimating the parameters of a log-linear production function whose variables are the four classes of
factor inputs defined for the accounting system described in Appendix B. The procedure also provides an estimate of the relative change in the price per unit of output (housing services). The data required by this procedure are the same as those required by the accounting system presented in Appendix B.

NOTATION

\( R \) = rental revenue received by producers of housing services, net of real-estate taxes.

\( p \) = price per unit of housing-service output, net of real-estate taxes.

\( n \) = number of units of housing-service output.

\( j \) = number of units of (generalized) factor-inputs.

\( k \) = number of units of capital inputs.

\( l \) = number of units of land inputs.

\( m \) = number of units of maintenance inputs.

\( n \) = number of units of building-service inputs.

\( \gamma, \alpha, \beta, \lambda, \delta \) = parameters of housing-service production function.

As in Appendix B, the quantities of factor inputs are measured for each building by deflating reported and imputed expenditure for each factor by an appropriate index of factor prices.

THE PRODUCTION FUNCTION

In our introductory exposition, as in Appendix B, we postulated a very simple production function whose implicit form is

\[ x = Q \alpha + \lambda + \gamma \lambda + \delta \lambda + \beta \lambda + \gamma \beta + \delta \beta + \alpha + \lambda + \gamma \lambda + \delta \lambda + \alpha \beta + \gamma \beta + \delta \beta + \gamma \lambda + \delta \lambda \]  

(C-5)

With this production function, an increase in output requires

\( \delta \) equivalent to \( \delta \), as defined in Appendix B.
Collecting the small second-order terms of the binomial expansion of
the right-hand side of Eq. (C-6) into a single variable $\lambda$, dividing by
Eq. (C-5), and subtracting 1 from each side, we arrive at the operationally convenient form,

$$\frac{\Delta \lambda}{\lambda} = \gamma \frac{\Delta \rho}{\rho} + \varepsilon.$$  \hspace{1cm} (C-7)

The parameter $\gamma$ in Eq. (C-7) could readily be estimated by the
procedures described below, and a single-parameter production function
may turn out to be adequate for practical purposes. However, using
the same data, we may be able to estimate the parameters of a more
detailed production function, one offering greater insight into the
production process:

$$\lambda = \lambda_0 \left( \lambda_0 + \frac{\Delta \lambda}{\lambda} + \frac{\Delta \rho}{\rho} \right).$$  \hspace{1cm} (C-8)

The production function given by Eq. (C-5) implies perfect substi-
tutability of the several factors, which may be approximately correct
over a limited range of factor mixes but clearly cannot be true for extreme cases. The production function given by Eq. (C-8) implies that
factors are imperfectly substitutable, with diminishing returns to any
one factor when the others are held constant. With a production func-
tion of this form, relative changes in outputs and inputs are given by

$$\frac{\Delta x}{x} = \frac{\Delta \lambda}{\lambda} + \frac{\Delta \rho}{\rho} + \frac{\Delta \lambda}{\lambda} + \frac{\Delta \rho}{\rho} + \varepsilon,$$  \hspace{1cm} (C-9)

where $\varepsilon$ represents a collection of small second-order terms of the
binomial expansion of each $\Delta \lambda$, $\Delta \rho$, and small cross-product terms
involving more than one $\Delta \lambda$.  

If we can estimate the parameters of Eq. (C-9), we are then able to describe the separate contributions of changes in each factor-input.

**ESTIMATING THE PARAMETERS**

Starting from the definition of net rental revenue,

\[ \varphi_n = \tilde{\varphi}_n \epsilon_n, \quad (C-10) \]

it can be shown that a change in rental revenue is equivalent to:

\[
\frac{\Delta \varphi_n}{\tilde{\varphi}_n} = \frac{\Delta \varphi_n}{\varphi_n} + \frac{\Delta \tilde{\varphi}_n}{\varphi_n} \tilde{\varphi}_n + \frac{\Delta \epsilon_n}{\tilde{\varphi}_n} \epsilon_n
\]

\[
= \frac{\Delta \varphi_n}{\tilde{\varphi}_n} + \left( 1 + \frac{\Delta \tilde{\varphi}_n}{\tilde{\varphi}_n} \right) \frac{\Delta \epsilon_n}{\tilde{\varphi}_n} \tilde{\varphi}_n. \quad (C-11)
\]

The production relationship given by Eq. (C-9) enables us to substitute inputs for outputs in Eq. (C-11) to obtain

\[
\frac{\Delta \varphi_n}{\tilde{\varphi}_n} = \frac{\Delta \varphi_n}{\varphi_n} + \left( 1 + \frac{\Delta \tilde{\varphi}_n}{\tilde{\varphi}_n} \right) \left\{ \frac{\Delta \beta_n}{\epsilon_n} + \frac{\Delta \theta_n}{\epsilon_n} + \frac{\Delta \gamma_n}{\epsilon_n} + \frac{\Delta \epsilon_n}{\epsilon_n} + \frac{\Delta \gamma_n}{\beta_n} \right\}. \quad (C-12)
\]

This notation may be simplified by letting

\[ p = \frac{\Delta \varphi_n}{\tilde{\varphi}_n}, \]

\[ \Delta \beta_n, \]

\[ \Delta \theta_n, \]

\[ \Delta \gamma_n, \]

\[ \Delta \epsilon_n, \]

\[ \Delta \gamma_n. \]

\[ p = (1 + \epsilon_n) \beta_n, \]

\[ p = (1 + \epsilon_n) \theta_n, \]

\[ p = C + \beta_n \theta_n. \]
\[ a_{\hat{Y}} = \hat{\hat{\beta}} + a_{\hat{\gamma}}/\gamma, \quad \text{and} \]
\[ a_{\hat{X}} = \hat{\hat{\beta}} + a_{\hat{\gamma}}/\delta. \]

Then Eq. (6-12) can be written in a form suitable for estimation by multiple linear regression,

\[ \eta = \hat{\hat{\beta}}_0 + a_{\hat{\gamma}} + \hat{\hat{\beta}}_1 \gamma + \hat{\hat{\beta}}_2 \delta + \hat{\hat{\beta}}_3 \zeta + \hat{\hat{\beta}}_4 \theta + \epsilon, \quad (6-13) \]

where \( \eta \) and the \( \gamma_j \) are observations for individual buildings, and \( \epsilon \) is the error term, including \( \zeta \).

If the regression enables us to estimate the intercept \( \hat{\hat{\beta}}_0 \) and coefficients \( \hat{\hat{\beta}}_1 \) of Eq. (6-13) with reasonable precision, they can be used in turn to estimate the parameters of the production function given by Eq. (6-8):

\[ \hat{\gamma} = \frac{\hat{\hat{\beta}}_0}{\hat{\hat{\beta}}_1}, \quad \hat{\delta} = \frac{\hat{\hat{\beta}}_2}{\hat{\hat{\beta}}_1}, \quad \hat{\zeta} = \frac{\hat{\hat{\beta}}_3}{\hat{\hat{\beta}}_1}, \quad \hat{\theta} = \frac{\hat{\hat{\beta}}_4}{\hat{\hat{\beta}}_1}. \quad (6-14) \]

The procedure also yields an estimate \( \hat{\beta}_0 \) of the average change in the price per unit of housing services across the sample.

While this procedure promises far better estimates of the parameters of the housing-service production function than are now available, we should also note several possible sources of inconsistency or bias in these estimators.

First, there may be some bias in the estimators of the intercept \( \hat{\hat{\beta}}_0 \) and coefficients \( \hat{\hat{\beta}}_1 \). The error term of Eq. (6-13) is known to include, the collection of second-order terms of the binomial expansion.
whose result is given in Eq. (C-9), and of the small cross-product terms involving more than one $\Delta y_{ij}$ from the same operation. As a consequence, the error term may be correlated with the independent variables, a condition that leads to inconsistent estimators.

Second, even if the $\hat{\delta}_2$ and $\hat{\delta}_3$ are unbiased maximum-likelihood estimates of the true parameters $\delta_2$ and $\delta_3$, our estimators of input elasticities ($\eta$, $\delta$, $\lambda$ and $\hat{\delta}$) are likely to be biased because each is a nonlinear function of two of the regression parameters. The nonlinear transformations entailed in Eqs. (C-14) would give rise to bias even if only one regression parameter were involved; when the transformation involves two regression parameters, their possible covariance is also a problem.

Finally, some of our colleagues argue that the estimators of input elasticities obtained by this procedure (or even by a procedure based on a strictly cross-sectional model such as a log transformation of Eq. (C-8)) are subject to simultaneous-equations bias; others are unconvinced, and the conclusions below do not reflect this argument.

**Conclusions**

To implement the procedure described above, we need only data on relative changes in rental revenue and relative changes in real factor-inputs (factor-expenditures in constant dollars) for individual properties. However, our data-set must have the following characteristics:

1. The relative change in rental revenue, $\Delta R_i/\bar{R}_i$, must vary substantially among properties.
2. The relative changes in each factor input, $\Delta z_{ij}/\bar{z}_{ij}$, must vary substantially among properties.
3. The ratios of relative changes among factor inputs must differ substantially among properties.

If the third condition does not prevail—that is, if producers vary all inputs proportionally—the multiple-factor production function is

*An inconsistent estimator is one whose sampling distribution does not converge on the parameter being estimated as sample sizes are increased.*
not estimable even if it is appropriate; but we can still estimate
the parameter \( \gamma \) of the single-factor production function given by
Eq. (C-5). In this case, the second condition is simply that relative
changes in total factor inputs, \( \Delta W_j / \bar{W}_j \), must vary substantially among
properties.

We expect the Supply Experiment to produce data satisfying the
first two conditions. At the beginning of the experiment, we know
that residential properties will vary widely in the amounts of revenue
they receive, in physical condition, and in quantities of factor in-
puts they use. The experimental allowance program will establish a
minimum standard for certifiability of housing units; since allowance
payments are conditional on the occupancy of certified housing, the
program should increase the demand for certifiable housing and de-
crease the demand for housing below the level of certifiability.
Owners of the latter type of housing can expect declining revenues
(more vacancies) unless they improve their properties to the standard
of certifiability.

For properties already above the standard, no improvements will
be needed to enable them to participate in the allowance-stimulated
market; and the increase in demand for such housing will enable them
to raise their rents to match the increase in market price, i.e.,

\[
\frac{\Delta R_j}{R_j} = \frac{\Delta R_k}{R_k}. \tag{C-15}
\]

For properties below the standard, the owners will be able to obtain
the higher price per unit of services, \( R_x + M_{ax} \), only if they also
increase their outputs. The necessary increase in output, \( M_{ax} \), de-
pends on how far below standard a property is initially, so it should
vary among properties whose owners elect to enter the allowance-
supported market from below. The revenue increase each thus obtains
will also vary, since it will reflect quantity changes as well as the
price change that motivated the housing improvement:
\[
\frac{\Delta r_n}{\Delta r_n} = \frac{\Delta P_n}{P_n} + \left\{ 1 + \frac{\Delta P_n}{P_n} \right\} \frac{\Delta t_n}{t_n}.
\] (C-16)

Finally, if these varying amounts of output change are undertaken, they will certainly require varying amounts of input change. Thus, both our first and second conditions for implementing the production function analysis should be satisfied by data from our sample of monitored properties.

However, the scenario we have just described suggests that the best sample of properties for this purpose would consist of (1) those beginning the experiment just above the standard of certifiability (price change, no output change); and (2) those beginning the experiment below standard but reaching the standard during the period of observation (both price and output change). Properties initially below standard that never reach the standard are never permitted to participate in the submarket in which the price per unit of services is \( P_n + \Delta P_n \); indeed, in their submarket, price is more likely to decline. Properties initially well above standard are unlikely to attract allowance-stimulated demand, because the minimum quantity of housing services offered to any one consumer is large; even at the preallowance price, and even with an allowance-sustained budget, few program participants will seek such housing, and output in this sector of the market is unlikely to change.

With the more limited sample described above, we have a good theoretical basis for assuming that \( P_n + \Delta P_n \) is indeed the relevant submarket price for a unit of housing services, so that individual households in that submarket who spend different amounts for housing are in fact buying different quantities. Of course, a "market price" is always an abstract concept with no precise empirical correlate: our measure of its change, \( \Delta P_n = \Delta P_n / P_n \), is as close as anyone is likely to get.

Finally, we should comment on the characteristics of the production function for housing services whose parameters are to be estimated by the procedure described above. The result of that analysis
will, of course, be an "average" production function for the population from which our sample of properties is drawn and will be pertinent only to production possibilities that can be implemented within the time span of our period of observation. Assuming that all producers in our sample face the same set of factor prices, the technical possibilities for increasing output faced by each producer will undoubtedly differ from those of his colleagues.

This does not necessarily mean that their production functions differ in the sense that \((a, \xi, \beta, \delta)\) take on radically different values in each case. It may mean simply that each producer, because of past irreversible decisions, is confined to a subspace of the production function. If he begins the period of observation with \(x_1 = x\), in the short run he is foreclosed from production methods that use either \(x_1\) or \(x/2\) to achieve the newly desired quantity of output. It is precisely the likelihood of this circumstance that leads us to hope that our data set may conform to Condition 2, above. The same circumstance leads us to expect that producers' rates of profit, as defined in Appendix B, will vary because their accessible techniques for producing a given amount of housing services will vary in efficiency.
Appendix D

ADJUSTING FOR REGIONAL AND LOCAL PRICE CHANGES

Section VI discusses in broad outline the way in which factor-price changes—changes in interest rates and in the prices paid for building improvements, maintenance inputs, and building services—will be accommodated in the analysis of supply response. Even if no other forces were at work, background inflation over the five-year period of the experiment could, if not properly accounted for, confound our interpretation of the experimental results.

In this appendix we present a three-step plan for measuring changes in the price of factor inputs, and for separating local from regional effects and allowance-induced from other local effects. First, we must measure the overall price change at each experimental site, so that expenditures for inputs during the experiment can be calculated in base-year dollars. Second, we must construct price indexes by which changes in regional, or background, price levels can be separated from the changes observed in local price levels. Third, we must devise a method for decomposing, with as much precision as possible, the local change—after accounting for background inflation—into allowance-induced and non-allowance-induced components.

MEASURING CHANGES IN THE PRICE OF FACTOR INPUTS AT THE EXPERIMENTAL SITES

As explained in Appendix B, it will be necessary to measure the overall change in the price of input factors used by each supplier of housing services at each experimental site. For analytical convenience, we propose to divide factor-price changes into four components: interest rates (the opportunity cost of capital), the price of capital improvements, the price of maintenance inputs, and the price of building services, each weighted by its share in total factor costs at baseline.*

The weights are shown in brackets in the following equation:

*See Eq. (B-18) in Appendix B and its associated text.
\[
\frac{\Delta P_p}{C_p} = \frac{\Delta P}{C} \left\{ \frac{\Delta P_{\text{land}}}{P_{\text{land}}} \right\} + \frac{\Delta P}{C} \left\{ \frac{\Delta P_{\text{fn}}}{P_{\text{fn}}} \right\} + \frac{\Delta P}{C} \left\{ \frac{\Delta P_{\text{mp}}}{P_{\text{mp}}} \right\} + \frac{\Delta P}{C} \left\{ \frac{\Delta P_{\text{sr}}}{P_{\text{sr}}} \right\} \tag{D-1}
\]

Below, we estimate typical weights for each component for some standard cases derived from recent data on factor costs for single-family houses and multiple dwellings. These estimates of the appropriate weights for each type of factor input enable us to judge the sensitivity of an overall factor-price index to changes in component factor prices, thus indicating the relative care with which each component should be price indexed.

Tables D.1 and D.2 show some of the data used in constructing our standard cases. They are empirical estimates of annual "occupancy costs" for single-family houses and units in multiple dwellings in the Northeast Corridor in 1968. Additional data for multiple dwellings in large U.S. cities in 1970, published by the Institute of Real Estate Management, were also consulted.

We used these data to construct the eight standard cases shown in Table D.3. The first four cases deal with single-family homes. Case 1 considers a new home that costs $20,000; Case 2, a well-maintained older home valued at $16,000; Case 3, an old home valued at $15,000 with minor rehabilitation of $1,000; and Case 4, a similar old house undergoing major rehabilitation costing $5,000.

The remaining cases represent units in multiple dwellings. Case 5 concerns newly constructed units at a cost of $15,000 per unit; Case 6, older, well-maintained units valued at $11,000 per unit. Case 7 introduces minor rehabilitation of $1,000 per unit; Case 8, major rehabilitation of $5,000 per unit, on older units valued at $10,000.

The estimated values of each of the weighting factors in brackets in Eq. (D-1) are shown for each case. The first two terms on the right-hand side of the equation represent interest charges on the value base.

* For convenience, all land costs are assumed to be included as part of the initial capital cost.

** This figure is the expected upper bound on allowance-induced rehabilitation (see Sec. VII). Because rehabilitation could be more extensive, we have included Case 4.

NOTE: Fractions may not add exactly to 1.00 because of rounding.
and on capital improvements. The last two terms represent maintenance and repairs and building-services costs, respectively.

To determine which component price changes most affect overall factor prices, we can calculate the overall change for a 10-percent change in each of the component prices. Practically, this requires only moving the decimal point one place to the right for each entry in Table D.3.

In all eight cases, the most important component is the value of initial capital and land, which determines the weight of the first component of Eq. (D-1), the interest rate. A 10-percent rise in \( \dot{r} \) will result in an overall increase in factor costs ranging from 4 to 8 percent among the eight cases. Clearly, accounting for interest-rate changes will be a very important part of the price-indexing scheme.

Changes in the price of capital improvements are much less important. In the two (more probable) cases dealing with rehabilitation expenditures of $1,000, a 10-percent price increase in the cost of capital improvements causes an overall increase in factor costs of only 0.45 and 0.54 percent, respectively. Even where rehabilitation expenditures are $3,000, a 10-percent price increase causes overall factor costs to increase by only 1.96 and 2.21 percent, respectively.

The last two components, maintenance and service, which are part of maintenance and operating costs, are indexed together. Although less important than the interest rate, they are considerably more important than the cost of capital improvements. In this case, a 10-percent change in the maintenance and service components together causes an overall increase in factor costs ranging from 2.17 to 4.35 percent, depending on the type of housing unit in question. Thus, in our price-indexing scheme, priority is given to interest rates and maintenance and operating costs. Capital-improvement costs, although of much less importance, must still be considered.

---

For example, consider a 10-percent change in the interest rate. Since all other prices are constant, \( \Delta P_m = \Delta P_w = \Delta P_s = 0 \). All of the right-hand terms except the first drop out of Eq. (D-1). The bracketed expression (corresponding to an entry in Table D.1) is multiplied first by .10, since \( \Delta \hat{I} = .10 \), and then by 100 to convert it to percent. This is equivalent to multiplying the bracketed expression by 10, thus moving the decimal point one place to the right.
importance than the other costs, are indexed to cover cases where there are large expenditures on rehabilitation.

Price Index for Interest Rates

Appendix B explains why the current rate of interest determines the opportunity cost of land and capital used for housing. The relevant interest rate here is that on residential mortgages. Since neither of our sites will include large cities, the number of financial institutions in the mortgage market is likely to be small. Hence, it should be feasible for Rand to monitor directly the interest rates on conventional first mortgages at each site. Some survey work will be necessary unless conventional mortgage rates are published locally.

Price Index for Capital Expenditures

The capital price index is less problematic because the experimental results are relatively insensitive to changes in capital prices. For input measurement, the capital values of the monitored properties will be appraised only in the base year; thereafter, the costs of capital inputs made during the course of the experiment (alterations, replacements, improvements) will be measured and must be deflated to base-year equivalents. As we have shown, the results of our analysis are relatively insensitive to changes in the prices of this group of factor inputs.

Therefore, it does not seem necessary to construct an index that measures changes in the specific costs of rehabilitating or altering residential structures. Rather, we can use an available price index of building construction costs. The Boeckh Building Cost Index* is published bimonthly for over 200 cities in the United States and Canada.**

---

*Published by the American Appraisal Company, Inc., Milwaukee, Wisconsin.

**It is very likely that the experimental sites will be covered by the Boeckh index. However, in the event that either (or both) is not, it appears that we will be able to contract with McGraw-Hill, Inc., to include our sites in their Bocckh Building Cost Index (a comparable, although less residentially oriented construction cost index) for a moderate sum. Because of their method of data collection, American Appraisal is unwilling to contract for cities not already included in the Boeckh Index.
The index is constructed from wage rates in 19 building trades and from prices for 64 types of materials. It is broken down into 11 different types of construction, including two types of residential construction. In our judgment, the latter are satisfactory deflators for our purposes.

**Price Index for Maintenance and Operating Expenditures**

An appropriate index for maintenance and operating (M&O) input prices is crucial to the correct interpretation of the experimental findings. Background inflation is likely to raise the price of M&O inputs by an average of 3 to 5 percent per year, more than enough to bias any conclusions about changes in housing costs resulting from the allowance experiment. Unfortunately, except for New York City, current M&O price indexes are not available and must be constructed when needed.

Basically, constructing an M&O index requires two steps: First, some way must be found for dividing M&O expenses into component categories, so that their relative weights in total M&O expense can be established for the type of housing being studied. Second, price changes in these categories must be estimated, or measured, and given weights. These weighted price changes are used to construct an index of price changes for overall M&O costs.

The first step, defining M&O expense categories and their relative importance, will be a by-product of surveys conducted during the experiment to monitor M&O inputs to housing production. Table 9.4 illustrates major M&O expenses and their fraction of total M&O expense for a typical rental building. These data are based on national averages collected by the Institute of Real Estate Management for 1,483 rental buildings in 1971.* Additional category breakdowns were made using data collected by the New York City-Rand Institute.** The M&O indexes constructed for the experiment will use percentage weights derived from site data.

The expenses in Table 9.4 are grouped into categories of relatively homogeneous goods and services. Within these categories, price changes

for component goods and services ought to be of comparable magnitude. Moreover, no price data are available for categories finer than those shown in the table.

There are three alternative methods for estimating M&O category price changes: (1) direct pricing, (2) specification pricing, and (3) finding a usable published index for the category. The direct-pricing method involves surveying the prices actually paid for inputs, for a sample of buildings. This method ensures that only strictly relevant evidence is being used, but it is vulnerable to error if changes occur in the quantity or quality of inputs purchased. Specification pricing seeks to overcome the quantity/quality-control problem by tightly specifying characteristics of the input under analysis and then estimating the supply price of a unit of input. Input prices may be estimated by surveying contractor estimates (e.g., for painting) or by calculating supply price from supplier formulas (e.g., for heating fuel).

The third method means, in effect, using information published by the BLS. Certain components of the Area Wage Survey (published annually for 1970 areas in the United States) and the Wholesale Price Index (published monthly for the nation as a whole) closely approximate our M&O expense categories. The relevant BLS index can then be used as a measure of price changes in each category. Since the third method of estimation does not involve survey costs, it is preferred for the purposes of the Supply Experiment. Inaccuracies introduced by matching BLS series components with M&O expense categories appear to be tolerable.

So far as we have been able to determine, however, there is no existing price index (BLS or other) for the categories of utilities and insurance. Local indexes covering these items may exist for the site cities, but a regional index is needed to net out background inflation. The best choice would therefore seem to be a combination of methods (2) and (3), above. We will use existing BLS indexes where possible and draw upon specification pricing to index the remaining categories.

---

* A discussion of the background-inflation problem is given below, on pp. 278-281.
Table D.5 repeats the M&O expense categories of Table D.4, adding the source index and the component that can be used in constructing our overall M&O index. Those categories in Table D.5 that list only the Area Wage Survey (AWS) are either chiefly labor inputs, which can be indexed with the appropriate AWS wage category, or inputs consisting of a significant amount of labor for which no corresponding commodity index exists. For example, management costs can be indexed by using the "Office Clerical Wage Index" of the AWS. Likewise, elevator repairs can be indexed by using the "Median Hourly Earnings Index" for maintenance mechanics, part of the AWS. *

Categories that are indexed from both the Wholesale Price Index (WPI) and the AWS involve significant amounts of materials as well as labor. Table D.5 notes the source indexes as appropriate and indicates how their data should be weighted. A more comprehensive and detailed description of this method of indexing is provided in Sternlieb's study of rental housing costs and revenues in New York City. **

Utilities, insurance, and several other services will be indexed by specification pricing. These categories are easy to price and involve only a small number of suppliers. The BLS publishes an index of operating costs for apartments in New York which illustrates how specification pricing is used and provides a useful list of specifications for utilities. *** Table D.6 gives an example of the BLS index for

---

* The AWS is not currently performed for every site of possible interest. In the event that the experimental sites are not covered by the AWS, we have two options: We can have the BLS survey the site(s) under special contract, or we can negotiate with the American Appraisal Company to purchase the wage and price data collected in the course of constructing the Bocchi index and use these data to construct an M&O index in its entirety.

** Sternlieb, op. cit.

SOURCE: Middle Atlantic Regional Office, Bureau of Labor Statistics, op. cit., Table 3.

Rent-stabilized apartments in New York City for 1972. Within the eight groups listed, the BLS used data from over 5,000 price quotations, based on a sample of about 60 specifically defined commodities and services, to compute price changes. Among the items priced are fuel oil, electricity, repainting a one-bedroom apartment, roof repairs, ledger paper, and light bulbs.

Table D.7 provides a historical perspective of M&O price changes. It lists the Boeckh index, wage-rate indexes, and the WPI construction-materials index for selected years since 1955. Residential-construction prices have increased by an average of 8 percent per year since 1967, wages by 11 percent per year, and construction-material prices by 5 percent per year.

SEPARATING THE EFFECTS OF BACKGROUND INFLATION FROM OBSERVED LOCAL PRICE CHANGES

Some of the price changes measured by the method described above will reflect background inflation—inflation occurring throughout the economy and thus not specific to the experimental sites. The background-inflation component can be factored out by comparing local factor-price changes with those for a larger surrounding area. This requires regional indexes comparable to our local indexes. We must start by defining the larger area to be covered by the regional index. It should bear some relation to the market area of the site, yet be large enough to escape significant influence by forces operating in local markets.

In the case of interest rates, we need an index of mortgage rates for the region. The Roy Wenzlick Research Corporation compiles local and regional data on interest rates gathered by surveying firms involved in the mortgage market. The compilations, which give the prevailing rate of interest on conventional residential mortgages on both a regional and a metropolitan level, are published annually in the Real Estate Analyst. The data are compiled separately for six regions and for many of the metropolitan areas within those regions.

We could either use an existing Wenzlick regional index or we could weight the rates for the various metropolitan areas within a specified region. The weighting scheme would be based on each city's share of the total lending volume in the region. Having both a local and a regional index of interest rates, we could subtract regional (background-inflation) changes from total local changes to obtain a net index of local interest-rate changes.

Construction of a regional index covering capital prices is relatively easy. Again, we must define the region to be covered by the index. If the Boeckh index is used as a capital-price index for the experimental site,* a regional index can be constructed by taking a population-weighted average of the Boeckh indexes for the cities within the region. The resulting index of background inflation could be subtracted from the local index of capital prices, giving an index of local price changes net of background inflation.

*The procedure would be unchanged if the Dodge index were used.
The procedure for preparing the M&O index is similar. Components from the AWS index can be population-weighted for cities within the region. Specification pricing would be done for the same cities used to weight the AWS indexes, applying the population-weighting procedure used there. Because the WPI is a national index, any regional index would be identical with our site index. This presents little cause for concern, since the materials indexed by the WPI are generally supplied in a national market. A local increase in demand for these materials would probably have no effect on their prices (although there might be temporary shortages in the site city).

Using the WPI and the population-weighted AWS and specification-price indexes, we can construct a regional index similar to that for capital inputs. This index could then be used to net out background inflation in the region.

As an example, consider the (likely) possibility that both experimental sites will be located in the north central portion of the United States. A map of this region, indicating the area to be covered by a regional index, is shown in Fig. D.1. The various shaded areas represent seven major trading areas as determined by Rand McNally. * We have combined these areas to form a region comprising most of Michigan, Wisconsin, Illinois, Indiana, and Ohio. The availability of the Boockh index and the AWS for various cities within the region is indicated in Fig. D.1 and Table D.3. In each case the data are sufficient to construct a population-weighted regional index. As indicated in Table D.8, Wenzlick provides interest-rate data for 28 cities in the region, which we could use should we decide to construct a regional interest-rate index.

---

*1972 Commercial Atlas and Marketing Guide, Rand McNally and Company, Chicago, 1972. The trading areas as defined in the atlas were "determined after an intensive study of such factors as physiography, population, newspaper circulation, economic activities, highway facilities, railroad services, suburban transportation, and field reports of experienced sales analysts" (p. 65).

</table>

SEPARATING ALLOWANCE-INDUCED FROM OTHER LOCAL PRICE CHANGES

Within the local housing market at each site, factor prices will be determined by derived or direct demand from three distinguishable sources: the demand for housing by allowance recipients, the demand for housing by nonrecipients, and the direct demand for those same input factors for entirely nonhousing objectives. For analytical purposes we may assume that the demand for housing by nonrecipients is independent of the allowance program. This assumption is not strictly correct, since the allowance program will have the side effect of raising incomes in the site, thus somewhat increasing all expenditures (including those on housing). However, this effect will be sufficiently small to be neglected in the analysis.

We must devise some means of measuring the price inflation caused by the experimental allowance program itself. It is possible that forces exogenous to the experiment will cause an increase in the demand for housing by nonrecipients, or in the demand for housing factors of production through the influence of some other, nonhousing market. Disentangling the three types of demand shifts that can take place is conceptually straightforward, though empirically laborious.

For the moment, let us focus on the market for housing by itself. Since nonrecipients and recipients compete for housing in the market, any increase in demand by nonrecipients will drive the price of housing up. This increase will be measured by the price-indexing scheme for the experiment, but it cannot rightly be attributed to the experiment (assuming, as we argue above, that allowance-program and nonrecipient housing demand are essentially independent).

Thus we need some method for removing the local inflation of factor prices caused by nonrecipient housing demand. Figure D.2 illustrates the supply of and demand for housing services. The quantity of housing services is measured along the horizontal axis and the price per unit of housing services along the vertical. The total demand curve for housing is broken down into demand by allowance recipients \( D_a \) and demand by nonrecipients \( D_n \).*

*Note that \( D \) is just the horizontal summation of \( D_a \) and \( D_n \).
Figure D.3 shows the situation when demand for housing by both recipients and nonrecipients increases (with a resulting increase in total demand). In each case, the demand curve representing the situation after the shift is marked $D'$. Conceptually, the relative contribution to price inflation of the two components of the demand increase is measured by the relative distance by which these curves shift to the right. If there has been an increase in demand, more units of a good will be purchased at a given price; the difference in the amounts purchased is a measure of the demand shift.

Since the experiment will monitor actual market situations, we will obtain data that determine points $a$, $c$, and $e$ (the quantities purchased at price $F_1$ before the demand shift) and points $g$, $h$, and $i$ (the quantities purchased at the new price, $F_2$, after the shift). However, the changes in quantities purchased, implicit in these points, will not give us information about the magnitude of the demand shift, since these quantity changes are not measured holding price constant. However, if we know the price elasticity of demand for housing and can
assume that it is constant in the range with which we are dealing, we should be able to determine the size of the demand shifts. We will know points $a$, $b$, and $c$ in Fig. D.3 as well as the price increase from $P_2$ to $P_3$; the price elasticity of demand will then allow us to determine points $d$, $e$, and $f$. *

We now have the information required to estimate the ratio of the increase in demand by allowance recipients to the increase in total demand. According to the definition given earlier, the total demand

As an illustration, let point $a$ in Fig. D.4 represent a quantity of housing denoted by $q_a$. Define the arc elasticity of demand with respect to price as

$$
\varepsilon(q_a) = \left( \frac{q_a - q_a'}{q_a + q_a'} \right) \left( \frac{P_a - P_a'}{P_a + P_a'} \right).
$$

We know $q_a$, $P_a$, $q_a'$, and $P_a'$, so it is only a matter of algebra to solve for $q_a'$. Then $P_a'$ and $q_a'$ determine point $d$ in Fig. D.2.
increase shown in Fig. D.3 is represented by the factor \( f' \). The demand increase of recipients is represented by the distance \( d_g \). Thus, the ratio \( d_g/distance \) of distance \( f' \) yields the proportion of total demand increase caused by allowance recipients.

Let us call local factor-price inflation \( \Delta F' \) (in reality, a different value for each factor \( f' \)); and call \( \delta \) the proportion of the total increase in demand for housing caused by allowance recipients.\(^*\) Then the amount of the factor-price inflation that can be attributed to a demand increase by allowance recipients can be estimated as \( \delta \Delta \), where \( 0 < \delta (\Delta F') < \Delta F' \).\(^**\)

Actually, \( \delta (\Delta F') \) is an upper bound on the amount of factor-price inflation caused by the experiment. The analysis above explicitly assumes that the only demand for factor inputs comes from the residential housing market. Thus, the entire price increase is apportioned to recipient and nonrecipient demanders of residential housing. Other economic sectors, of course, use the factors for which we are constructing price indexes; it is possible that some of the price increase can be accounted for within those sectors.

The possible alternative uses of factor inputs at the test sites, and the intensity of their employment, are not known at present. Table D.4 suggests that in most cases either nonhousing consumption is relatively small or the factor price in question is not sensitive to local market prices. Approximately 20 percent of M&O expenses concern utilities and insurance, the prices of which are determined by regulatory bodies. Heating fuel, which accounts for 11 percent, while not directly price-regulated, is sold in a larger regional market and is unlikely to

\(^*\) Note that \( \delta \) is a fraction whose value lies between 0 and 1 inclusive.

\(^**\) In a strict sense, this statement may not be correct. It is based on the fact that the demand for factor inputs is derived from the demand for housing services. Only if the factors are used in fixed proportions (which is probably less true in the short run than in the long run) can the demand for the final product (housing) be apportioned to the various inputs. If factors are not fixed and if the apportionment changes, pressures on the prices of different factors will vary. In view of possible measurement errors in our other data, however, we think that the calculation is sufficiently precise to yield a good approximation.
fluctuate in price appreciably with a shift in nonhousing demand at the sites. Management costs are nearly 13 percent of the total, but the suppliers are probably specialized to the housing market. The categories of miscellaneous repairs, plumbing and heating, elevator service, and janitorial service may not be wholly specialized to housing; these amount to about 16 percent of total N&O cost and are probably the factors most sensitive to nonhousing demand shifts. We conclude that vigorous and unlikely shifts would have to take place in nonhousing-market sectors before factor prices would be significantly affected in the aggregate.

Hence, we believe that it is not worth the additional effort to isolate demand shifts in nonhousing sectors. We will instead attribute all locally caused price changes to shifts in housing demand. A fortiori, the allowance-induced price rise will not be greater than this estimate.

In terms of Fig. D.1, \( dP_{r,h} \), the amount of factor-price inflation caused by the housing market, will be less than \( dP_{r} \); thus \( e(dP_{r,h}) \leq e(dP_{r}) \). Since \( e(dP_{r,h}) \) is what we are really trying to measure, \( e(dP_{r,h}) \) will be an upper bound on the amount of inflation caused by the experiment.

To complete the above analysis we will need certain data, most of which will be generated in the course of the experiment. The necessary data are the prices of housing services, changes in the total quantity of housing services purchased and separation of these changes into changes in the amounts purchased by allowance recipients and nonrecipients, and the price elasticity of the demand for housing services. The prices of housing services will be measured as explained in Appendix B.

The total quantity of housing services purchased can be estimated from survey data obtained for our panel of residential properties, which will be a probability sample of the entire housing stock. N&O administrative records will give exact figures on expenditure changes by allowance recipients. Deflating expenditure changes by the previously indexed price changes will yield the changes in quantity purchased. Subtracting changes in quantities purchased by recipients from total quantity changes gives changes in quantities purchased by nonrecipients.
The price elasticity of the demand for housing services will be mapped by the Demand Experiment. We propose to use the elasticity function thus estimated in this analysis despite the fact that the estimate will be based on data for cities other than our sites. To the extent that we question the exact appropriateness of these "borrowed" functions, we will resort to a fortiori analysis, showing results for approximations that are most favorable and least favorable to the allowance program.
Appendix E

ANALYTICAL INTEGRATION OF DATA FROM THE
DEMAND AND SUPPLY EXPERIMENTS

Although conducting the Demand and Supply Experiments as separate operations makes good sense to us, and conducting them at different sites is necessary to the success of each, one of the possible penalties is that they might develop design features that interfere with subsequent analytical integration of their findings.

In designing the Supply Experiment, our main consideration has been to devise an experimental setting from which credible evidence about the effects of a housing allowance program could be obtained. To the extent that the experimental evidence plays a part in future legislative processes, we think that the critical question that will be addressed to the monitors of the Supply Experiment is, What happened in City X and City Y as a consequence of the experimental programs mounted there? It is no easy task to devise monitoring procedures that will enable us to answer this limited question in a convincing way. If our experimental design accomplishes that much, it will have accomplished a great deal.

The broader question is, What would happen in other cities or in the nation if a national housing allowance program were implemented? We would in fact expect our audiences, in both the executive and legislative branches, to draw their own general conclusions from the evidence presented for the experimental sites, whatever arcane extrapolations were offered by analysts.

Nonetheless, there is a smaller audience, perhaps equally important, that is concerned about scientific techniques for generalizing from limited experimental evidence. The exposition below is addressed to this audience. Here, we try to show how the data from the Demand and Supply Experiments could be combined analytically to permit estimation of:

1. The effects of tested allowance programs on the market price of housing services in housing markets other than the experimental sites,
2. The effects of variations on the tested allowance programs in such markets, and
3. The effects of the estimated price changes on the quantities of housing services consumed by allowance recipients and nonrecipients.

The basic structure of the analytical model here proposed can be summarized as follows: The data gathered in the Demand Experiment should enable us to estimate individual parameters of demand response to price that vary with observable household characteristics, including household income and allowance entitlement. The data gathered in the Supply Experiment should enable us to estimate individual parameters of supply response to price that vary with the characteristics of the supplier and his property. If these parameters of individual behavior are expressed in terms that are reasonably independent of the particular housing-market context in which they were observed, they should have broader applicability to the behavior of similar individuals elsewhere; in other words, the behavioral parameters will be more or less "portable."

Carrying these behavioral parameters to a local housing market other than those that served as sites for the Demand and Supply Experiments, we can apply the appropriate demand parameters to each household in that market. The effects of a hypothetical allowance program on each individual's housing demand can be estimated from program rules as to eligibility and allowance entitlement. For each household in the new site, whether an allowance recipient or not, we can thus construct a schedule that describes the quantity of housing services it would demand at alternative prices. These individual schedules can be aggregated to form a market demand schedule.

A similar procedure can be followed for suppliers at the new site, constructing for each a schedule that describes the quantity of housing services it would supply at alternative prices. These individual schedules can be aggregated to form a market supply schedule.

Comparing the market demand schedule and the market supply schedule, we can estimate the price for housing services that would clear
the market—i.e., the price at which the quantity demanded would equal the quantity supplied. Once this price is determined, it can be substituted into individual demand and supply schedules to estimate the quantities of housing services that would be demanded or supplied by individuals with specified characteristics, given the market-clearing price.

The general framework of this analysis is thus easily described. Working out its details in the context of the data we expect to obtain from the Demand and Supply Experiments is another matter. Below, we give a provisional sketch of these details, one which falls short of resolving either the conceptual or the operational problems, but which at least suggests strategies that might be employed. We try to show, in principle, what could be done, given "clean" and comprehensive data from the experiments. Actually, the data will be both "dirty" and incomplete; at best, we can hope for a crude approximation to the data needed to implement the analysis here described. But the data requirements of the analytical model will at least serve as a target for experimental design; and, if HUD wishes to pursue analytical integration of data from the two experiments, the sketch given here of the analytical model will serve as a point of departure for its systematic development and articulation.

THE DEMAND EXPERIMENT

In the Demand Experiment, a thin sample of low-income families living in one or more large metropolitan areas will be selected for enrollment in a housing allowance program. Subsamples of enrollees will be given allowances on different terms, and their housing choices and budgetary decisions will be monitored for a period of three years. Because the number of allowance recipients will be small relative to the population of the housing market, increased housing expenditures by allowance recipients will not add up to significant demand pressure. No measurable supply response, in the sense of a change in the price of housing services or in the quantity supplied, can be anticipated as a consequence of the experiment.

As we understand the plans for the Demand Experiment, treatment variations will include two basically different allowance formulas:
1. **Housing-gap formula.** Participants receive allowances equal to a specified percentage of their disposable incomes.

2. **Housing-discount formula.** Participants receive allowances equal to a specified percentage of their contract rents.

Under the first formula, allowance payments may be earmarked directly or indirectly for housing expenditure. Under both plans, the percentage contributions by the government will be varied.

The assumed lack of significant supply response makes it possible for the Demand Experiment to capture two vital kinds of information: estimates of the income elasticity of housing demand and of the price elasticity of housing demand. Allowance recipients will be able to purchase housing services at the going market price, and their purchases will not significantly affect that price. Thus, any increase in their housing expenditures subsequent to enrollment can be interpreted as an increase in the quantity of housing services consumed.*

An allowance program may affect the recipient's income, or the price that he pays for a unit of housing services, or both. Under a housing-gap allowance plan, his income is increased by $a^G$, but the price he pays for housing services is the market price. Under a housing-discount plan, he gets a discount on the market price of housing services, paying only $a^D$ per unit of service: simultaneously, he gets an increase in income equal to the public contribution to his rent, $(1 - \delta)^G$. For different subjects in each treatment class, $a$ and $\delta$ will be varied.

By careful selection of subjects and by systematic variations in treatments, the Demand Experiment should be able to obtain the data needed to estimate the parameters of two household response functions whose general forms are shown below:

\[
\frac{\frac{\partial u}{\partial y}}{\frac{\partial u}{\partial x}} = \alpha, \beta, \gamma, \delta, \eta, \phi. \tag{E-1}
\]

and

\[
\frac{\frac{\partial u}{\partial x}}{\frac{\partial u}{\partial y}} = \alpha, \beta, \gamma, \delta, \eta \tag{E-2}
\]

*This interpretation assumes that there is no change, over time, in the market price of a unit of housing services due to factors other than the experimental program, so a requirement for unbiased estimation of the elasticities discussed below is a system for deflating market rents to a constant-dollar basis. For similar reasons, the incomes of allowance recipients must be adjusted to take into account changes in the consumer price index.
where $\delta$ = quantity of housing services demanded by the household: 
$\nu$ = a vector of household characteristics; 
$\vartheta$ = a vector of dummy variables representing alternative earmarking provisions; 
$\tau$ = time since enrollment; 
$Y$ = disposable income; and 
$SF$ = the unit price of housing services to the allowance recipient; $F$ is arbitrarily set equal to $\delta$.

We assume that these functions would be fit by multiple regression on cross-sectional data for each of a series of postenrollment years. With their aid, it is possible to map the demand response over time to changes in either $\nu$ or $F$, or both, for any household whose characteristics, $\nu$, are known. If changes in $Y$ are induced by a housing-gap allowance program, we would also need to know the earmarking provisions. If the allowance program is a housing-discount plan, we would of course need to know the discount rate, $(1 - \delta)$. In general, Eqs. (E-1) and (E-2) can be combined and transformed into a household demand function, with time $(\tau)$ in the argument:

$$\delta = g(\nu, A, \tau, Y, F).$$  \hspace{1cm}  (E-3)

Furthermore, if we can assume mutual independence of household preference functions, we can aggregate housing demand as a function of price over any set of households for each of which $\nu$ and $\tau$ are known. Hereafter, we will let Eq. (E-3) stand for this aggregate, rather than individual, demand function; a more accurate notation would use summation signs to achieve this result.

THE SUPPLY EXPERIMENT

In the Supply Experiment, two metropolitan areas will be selected as sites. In each, a full-scale housing allowance program will be mounted, enrolling all those likely to be eligible in a national program of this type. At both sites, the same allowance formula will be used; it will be a housing-gap formula, and allowances can be used only in housing certified as meeting minimum standards.
Within these sites, we propose to monitor changes in rental revenues and changes in the flow of housing services for a period of five years. Separate accounts will be carried for individual structures whose owners' characteristics will be identified, as well as the characteristics of the tenants and the neighborhoods in which the structures are located. We propose to concentrate our sampling resources on structures whose rents (or market values) are within reach of allowance-augmented budgets, i.e., structures for which changes in rental revenues due to the allowance program are probable.

We have devised a method for estimating changes in the flow of housing services from these structures, based on systematic accounting for changes in real factor inputs and certain assumptions about the characteristics of the production function. With its aid, we can decompose observed changes in rental revenues, as follows:

\[
\frac{\Delta r}{r} = \frac{\Delta s}{s} + \frac{\Delta q}{q} + \frac{\Delta r_{i}}{r_{i}}, \tag{E-4}
\]

where \( r \) = base-year rental revenue;
\( s \) = base-year quantity of housing services supplied to the market; and
\( p \) = base-year price per unit of housing services.

We are further able to decompose the estimated change in the price of housing services into components reflecting observed changes in factor costs per unit of output (including the opportunity cost of capital inputs) and changes in the owner's rate of return on cost of production:

\[
\frac{\Delta s}{s} = \frac{\Delta q}{q} + \frac{\Delta r_{i}}{r_{i}}, \tag{E-5}
\]

See Appendix B for details of the accounting system; it assumes that changes in output are proportional to changes in real factor inputs. Appendix C proposes a method for testing this assumption and adjusting our results if it proves substantially incorrect.

Below, we generally follow the notation of Appendix B, but we have simplified it to avoid excessive subscripting and to suppress distinctions irrelevant to the present discussion.
where $F = \text{factor costs per unit of output}$; and

$\bar{m} = P/F = \text{producer's markup on factor costs}$.

Since $\Delta$, our measure of the quantity of housing services supplied, includes vacant available units as well as occupied ones, and $P$ is actual net rental revenue for the structure, $\bar{m}$ is a building-wide average price for housing services that will vary not only with rent levels but with vacancy rates. So our observations on individual structures should give us plenty of variation in $\Delta \bar{m}/\bar{P}$, with which we can associate observed changes in output, $\Delta q/\bar{Q}$.

We wish to use these data to estimate a supply response function corresponding in form to Eq. (E-2). In principle, this function should describe the amount by which a producer would change his output for a given change in its expected market price, all other things equal. With a certain amount of behavioral modeling, our data will serve.

First, we need an estimate of the producer's supply response to an expected change in its market price, whereas our observations of $\Delta \bar{m}$ and $\Delta \bar{P}$ are after-the-fact. Landlords who misinterpret market signals may be either pleasantly surprised or disappointed by the consequences of their production decisions. A plausible behavioral model is that output in year $t$ reflects decisions made in year $(t - 1)$, based on prices then prevailing; in estimating our response function, we should lag one period behind $\Delta$ or perhaps use a distributed lag.

Second, we seek a partial derivative of supply with respect to price, all other things equal. Most pertinently, these "other things" include the available technologies of production and the costs of the various factors of production, which together determine the producer's costs at various levels of output. Our observed responses do reflect price changes, but they may also reflect changes either in methods of production or in factor prices, limiting their relevance to contexts in which changes in the market price of output are accompanied by the same set of technological possibilities and the same set of factor costs.

We do not think that technological innovations during the five years of the Supply Experiment are likely to much alter the options of
producers of housing services, constrained as they will be by the technology embodied in the existing stock of housing; but production alternatives, hence supply responses to price changes, are likely to vary among producers, depending on the characteristics of their existing structures. So baseline structure characteristics should enter as explicit variables in estimates of supply responsiveness for individual producers, either as regression variables or as stratification variables.

Factor prices, on the other hand, are likely to change over time during the experiment, but not to vary among producers at a given time.* In order to estimate how the producer would respond to price changes alone, we must adjust our observed $\Delta F$, discounting for the changes in factor-costs that occur over the period in question.** As suggested by Eq. (E-5), this can be accomplished by substituting $\Delta K$ for $\Delta F$ in the supply function, noting that in the absence of changes in factor prices, $\Delta K = \Delta F$.

Finally, we presume that the producer's skill, his expectations, and his resources may affect his response to changes in the market price of his output for other reasons than those already indicated. So the argument of our supply response function should contain

---

*Cross-sectional variations are possible, either in the form of lower prices for bulk purchases, or in the form of price discrimination in an imperfect factor market. In either case, we would expect cross-sectional variations in factor prices to be regularly associated (in our experimental sites and elsewhere) with structure, landlord, and neighborhood characteristics; if so, building these variations into estimates of supply responsiveness that are specific to housing-market sectors does not much reduce the generality of the response function.

**As explained in Appendix D, factor prices will be indexed at each site and site-specific components of change will be distinguished from regional or national components of change. To the extent possible, site-specific changes due to the allowance program will be distinguished from those attributable to other events in local markets.

For present purposes, the total observed change in factor prices at the experimental site is the appropriate discount, whatever the components of change. We do not expect the increment of housing-service production caused by the allowance program to have a significant impact on factor prices; if it does, the market model described below would require an additional equation to estimate the effect of changes in the level of housing-service production on factor prices.
variables describing the landlord, his building, and its neighborhood that (1) are statistically associated with response differences among producers, and (2) whose values can be estimated for places other than the experimental sites.

The considerations reviewed above lead us to a functional form that is reasonably consistent with our purposes and whose parameters can be estimated by multiple-regression analysis of cross-sectional data for individual properties monitored in the Supply Experiment:

\[
\frac{q_i - q_i^*}{q_i} = \beta_1 + \beta_2 \gamma_i + \beta_3 z_i + \beta_4 \delta_i + \epsilon_i
\]  

(6-6)

where \( q_i \) = output of housing services during year \( t \);

\[ \bar{p}_i = \frac{q_i}{r_i} \] = producer's actual* markup on factor costs during year \( t \);

\( e_i \) = average price received per unit of output during year \( t \);

\( f_i \) = average factor cost per unit of output during year \( t \);

\( \beta, \gamma, \delta, \epsilon \) = a vector of building characteristics as of year \( t \);

\( \gamma, \delta, \epsilon \) = a vector of landlord characteristics as of year \( t \); and

\( \beta, \gamma, \delta, \epsilon \) = a vector of neighborhood characteristics as of year \( t \).

The expression on the left-hand side of Eq. (6-6) is the observed supply response of one producer for year \( t \). Its numerator measures the percentage by which his output increased between the base year and

*As distinguished from his expected markup, which would be based on expected prices for output and factors of production, i.e.,

\[
E \left[ \frac{q_i}{r_i} \right] = \frac{E \left[ q_i \right]}{E \left[ r_i \right]}. 
\]
year $t$; its denominator measures the percentage by which this profit margin increased between the base year and year $t - 1$. We thus assume that his most recent experience with market conditions governs his production plans for year $t$.

The right-hand side of the equation offers the hypothesis that a producer's output response to a change in profit margin is conditional on the variables there specified: the base-year characteristics of the building, the landlord, and the neighborhood; the base-year level of output; and the base-year markup rate. The purpose of the proposed regression analysis is to estimate the parameters of the partial relationships between observed supply response and each variable in the argument of the function.

If these parameters can be estimated with reasonable precision on a sample of properties varying with respect to $z_d$, $z_g$, $z_e$, and $z_1$, for periods $t = 1, 2, 3, \ldots$ of varying distance from baseline $t = 1$, they will help us to model a "behavioral" supply function for an individual producer. The general form of such a function would be:

$$z_t = z\left(\frac{z_d}{z_g}, \frac{z_e}{z_d}, \frac{z_1}{z_d}, \frac{z_g}{z_1}, \frac{z_1}{z_g}, \bar{z}_d, \bar{z}_g, \bar{z}_e, \bar{z}_1, \bar{z}_d, \bar{z}_g\right). \tag{L-7}$$

Here, $z_t$ is the planned level of output for year $t$, which is related explicitly to the base-year circumstances by the producer and to expected prices for output and expected costs of production in year $t$. The derivation of Eq. (L-7) from a fitted version of Eq. (L-6) entails both mathematical manipulation of the terms of Eq. (L-6), the nature of which depend on its actual functional form, and the assumption that \( \bar{z}_d = \bar{z}_g \). While it is not hard to imagine practical complications in going from Eq. (L-6) to Eq. (L-7), their seriousness cannot be easily assessed prior to specifying the functional form of Eq. (L-6).

If we are further willing to assume mutual independence of landlords' responses to market signals, we can aggregate over any set of landlords for each of whom $z_d$, $z_g$, and $z_e$ are known in any local market for which factor costs $z_1$ are known; these known quantities will define the relationship between the preferred level of output and the price of housing services for each producer, and these individual supply
schedules can be added to obtain an aggregate supply schedule as a function of price. Hereafter, we will let Eq. (E-7) stand for such an aggregate supply function; for convenience in exposition, we will also drop the subscript detail, relying on the reader's memory to fill out the generalized relation,

\[ s(i, j, n, d, f, p) \]

(E-8)

ANALYTICAL INTEGRATION

Suppose we now consider a local housing market other than those in which the Demand and Supply Experiments were conducted. Assume that we are able to describe the structure of that market, both with respect to the characteristics of housing consumers \( h \), their incomes \( i \), and their total housing expenditures \( e \); and with respect to the characteristics of its housing inventory \( z \), its landlords \( l \), and its neighborhoods \( n \). We wish to estimate the effects of a housing allowance program—either a housing-gap allowance or a housing-discount allowance—on the price and quantity of housing services in the local market.

We may begin by describing the state of that market before the hypothetical allowance program is installed. From Eqs. (E-3) and (E-8) we can form a market-clearing equation of the following form:

\[ i(e, z, n) = s(i, j, n, d, f, p) \]

(E-9)

where \( i = j = n = e \) is the quantity of housing services that clears the market—not in the sense of eliminating all vacancies, but in the sense that landlords continue to offer the vacant units for rent rather than withdrawing them from the market.

Although the Demand and Supply Experiments provide us with estimates of parameters for all of the variables in Eq. (E-9), the units of account for some of these variables were arbitrarily defined at each experimental site. To combine them in Eq. (E-9), and to apply Eq. (E-9) to housing markets other than the experimental sites, we must adjust all such variables to common units of account. The problem involves
$Y$ and $\hat{Y}$ in the demand function and $\hat{P}$ and $P$ in the supply function and is resolvable with the aid of price indexes.

First, we will need a consumer price index to transform $Y_n$ as measured at the new site to dollars whose purchasing power is equivalent to the dollars in which $Y_d$ was measured in the Demand Experiment. Where $t$ is the appropriate deflator, we can then use $t \cdot Y_n$ as an argument in the demand function whose unit of account is consistent with the fitted parameters.

Second, we will need an index relating factor prices in both the Demand and Supply Experiments to those of the new site. Such an index will enable us to adjust both $\hat{F}$ and $F$ to common units of account, as explained below.

To fit the parameters of our demand function, we first arbitrarily set the baseline market price of housing services, $F_d = \bar{F}$, so that the quantity of housing services demanded could be measured by

$$\hat{Q}_d = \frac{F_d}{P}$$

(E-10)

where $\hat{Q}_d$ is total housing expenditures in current dollars. Once the unit of measurement for $\hat{Q}_d$ was thus defined, the variations in price needed to measure demand response were achieved by charging allowance recipients only $B \cdot P_d$, varying $B$; covariation of $\hat{Q}_d$ with $P_d$ could then be observed and is the analytical equivalent of varying $P_d$.

In the Supply Experiment, our system of measurement, as explained in Appendix B, is generally designed to avoid the necessity of specifying the unit of account for housing services; it deals in relative changes only. Implicitly, however, that unit of account is defined by

$$Q = \frac{Y}{P}$$

(E-11)

where $Y$ is total expenditures for factors of production at baseline and $P$ is the unit price of a composite factor of production, arbitrarily setting $P = \bar{P}$. With $Q$ thus defined, it follows that
\[ F_0 = \frac{E}{Q_0}, \quad (E-12) \]

where \( F_0 \) is total revenue from the sale of housing services. As factor prices change over time, we index them \( \gamma = \lambda F_0 \); the index is then used to deflate total factor expenditures in current dollars, preserving the same unit of account for housing services:

\[ \tilde{F}_0 = \frac{F_0}{F_0} = \frac{F_0}{F_0}, \quad (E-13) \]

where the prime symbols indicate observations at a later date, and remembering that \( F_0 = \lambda \).

Under certain assumptions, this technique of indexing factor prices enables us to establish a common unit of account for \( \gamma, \lambda \), and \( \gamma \), where \( \gamma \) is the quantity of housing services that clears the market at our "new" site. The assumptions are as follows:

1. At all three sites, households with the same specified characteristics \( \mathcal{H}, \mathcal{V} \) have the same demand for housing services relative to their price.
2. At all three sites, landlords with the same specified characteristics \( \mathcal{B}, \mathcal{E}, \mathcal{M} \) are willing to supply the same amount of housing services, given a specified market price and a specified factor cost per unit of output.
3. At all three sites, landlords with the same specified characteristics \( \mathcal{B}, \mathcal{E}, \mathcal{M} \) face the same production function.

First, we adjust for factor-price differences among the three sites, just as in Eq. (E-13) we adjusted for factor-price changes over time. Letting \( \gamma = \gamma \), for a fixed bundle of factors \( Q \), we can directly measure \( F_0 \) at each site and calculate deflators \( \gamma \) and \( \lambda \) such that:

\[ \tilde{F}_0 = \gamma \tilde{F}_0 = \lambda \tilde{F}_0. \quad (E-14) \]
Then, if we take the output quantities $\gamma_d$ and $\tilde{\gamma}_d$ as originally measured at each site, it follows that equivalent values at the new site are defined by

$$\gamma_d = \gamma_d = \lambda \tilde{\gamma}_d.$$  \hspace{1cm} (E-15)

then, from Eq. (E-12), equivalent prices for housing services are defined by

$$P_y = \gamma^{-1} \frac{\gamma}{\gamma_d} = \lambda \tilde{\gamma}_d.$$ \hspace{1cm} (E-16)

Making the appropriate substitutions in the arguments of our demand and supply functions, our market-clearing equation becomes

$$\gamma^{1/\gamma_y}, \gamma^{1/\gamma_d}, \gamma^{1/\gamma_y} = \lambda \gamma^{1/\gamma_y}, \lambda \gamma^{1/\gamma_d}, \lambda \gamma^{1/\gamma_y}.$$ \hspace{1cm} (E-17)

However, to simplify notation once again, we will assume that all the appropriate adjustments in units of account have been made and return to the unsubscripted notation of Eq. (E-9).

**MARKET EFFECTS OF AN ALLOWANCE PROGRAM**

To estimate the effects of a housing allowance program on the price and quantity of housing services in the local housing market described above, we must alter the arguments in our demand function to reflect the specifications of the allowance program, then find the price at which the demand for and supply of housing services would be equal. The procedure differs for a housing-gap allowance program and a housing-discount allowance program.

**Housing-Gap Allowance Program**

A housing-gap allowance formula provides for allowance payments equal to a specified percentage of disposable income, the percentage dropping to zero as income increases; if it is to be other than a general income supplement, it also must earmark some or all of the allowance payment for housing expenditures.
For a given household population whose incomes are known, we can estimate the change in income ($\Delta I$) that would result from a specified housing-gap allowance program; together with the earmarking provision ($A$), this change in income will determine how demand responds to the market price of housing services ($P$):

$$\bar{Q}_d = N(e, \lambda, P + \Delta I, P).$$

(E-18)

The allowance program has no effect on the argument of our supply function:

$$Q_g = S(P, \lambda, \sigma, F, P).$$

(E-19)

For the specific local market, we know the baseline characteristics of the housing stock, landlords, and neighborhoods ($F$, $\lambda$, and $\sigma$); the unknowns are factor prices ($F$) and the price of housing services ($P$). Finally, we need a market-clearing equation,

$$\bar{Q}_d = \bar{Q}_s.$$  

(E-20)

We would propose to solve this system of three equations in four unknowns by predicting a value for $F$, the solution then being conditional on the accuracy of that prediction. As noted earlier, a priori analysis of incremental factor-demands associated with plausible levels of allowance payments lead us to doubt whether factor prices will be much affected by a local allowance program;* and even in the case of a national allowance program, we would expect program effects to be swamped by independent events in national factor markets—particularly, in capital markets. We doubt that much reliability would be gained by modeling

$$F_i = \mathcal{M}(i).$$

(E-21)

*See Appendix D.
from data gathered by the Supply Experiment, but it remains a possibility if we find evidence of substantial allowance-induced inflation in factor prices.

In reduced form, our market-clearing equation is solved by finding \( \Delta F \) such that

\[
0 = H, A, \Delta H + F, F + \Delta F, \Delta F, H + \Delta F, F + \Delta F.
\]  

(E-22)

Comparing the solution values of \( \delta = 3 = \xi \) for this case to those of Eq. (E-9), with preallowance values, we can measure the relative change in the flow of housing services (\( \Delta X, \xi \)) resulting from the allowance program and the associated change in the average price of housing services (\( \Delta P, F \)). Using the marketwide solution value of \( F + \Delta F \) as an argument in the demand function, we can also estimate how housing consumption would change for particular classes of households (e.g., recipients vs. nonrecipients).

**Housing-Allowance Program**

For an allowance program employing the housing-discount formula, the solution is more complicated. First, the effective unit price of housing services to allowance recipients differs from the unit price to nonrecipients and to suppliers of housing services. Second, the amount of the income change for allowance recipients cannot be computed a priori; the income change consists of a refund on their housing expenditures, and the amount of these expenditures cannot be deduced solely from program regulations.

As noted earlier, under a housing-discount formula, the price of a unit of housing services to the recipient is \( \delta \), \( \delta = 3 \); for nonrecipients, \( \delta = 1 \). Therefore, in constructing our marketwide demand function, we must aggregate individual demand functions of the form

\[
G_{i,j} = F_{i,j}, F + \Delta F, \xi + \Delta F,
\]

(E-33)

in which both \( \Delta F \) and \( \frac{1}{\theta} \) are variables. Therefore, we need an additional equation,
\[ \Delta \bar{Y} = \gamma_{1-\gamma} \]  

(E-24)

which says that the change in income as a result of the allowance program is equal to the amount of the refund on actual housing expenditures by allowance recipients.

Our reduced-form market-clearing equation is then

\[ \beta \left[ S, Y+(1-\gamma)\left(\gamma+\Delta N, \beta \gamma \Delta N \right) \right] = F \left[ k, z, x, F+\Delta F, F+\Delta F \right], \]  

(E-25)

which can be solved for \( \Delta F \) as before, conditional on a predicted value for \( \Delta F \).

CONCLUSIONS

In principle, the data from separately conducted Demand and Supply Experiments can be combined analytically to estimate the consequences of either a housing-gap or a housing-discount allowance program applied to a housing market other than those that served as experimental sites. The application of the principle, however, is extremely complicated; the exposition above bristles with unresolved technical issues and, as we have discovered on each review, with hidden assumptions. We offer it only as a general analytical plan that could be pursued at various levels of sophistication. Its critical features can be simply stated:

1. Household responses to the allowance program, observed in the Demand Experiment, can be made reasonably portable by relating them to household characteristics, income, and the price of housing services.

2. Supplier responses to the allowance program, observed in the Supply Experiment, can be made reasonably portable by relating them to the baseline circumstances of the individual producer, the price of housing services, and the cost of producing them.

3. To estimate the effects of an allowance program in any given local housing market, these portable parameters of demand and
supply responses can be applied to the local population of
demanders and suppliers, if their relevant characteristics
are known.

4. Given local factor prices, the market-clearing price and
quantity of housing services can be estimated by aggregating
demand and supply responses to price changes over the rele-
vant local populations of demanders and suppliers.

Our principal reservations about this method for analytical
integration and extension of site-specific findings can also be sum-
marized briefly:

¢ On both the demand side and the supply side of the market,
it must be assumed that each participant responds indepen-
dently to market signals, so that individual supply and
demand functions can be aggregated.

¢ It must be assumed that the arguments of the demand and
supply functions include all the relevant variables. Those
that are likely to be omitted are "background" variables,
general characteristics of the experimental sites. In
both experiments, the number of sites is too small to pro-
vide enough variation in these variables to allow them to
be used for parameter estimation, but sites are being se-
lected deliberately for such differences, so that there
will at least be some evidence that our response param-
eters are either stable or unstable under different back-
ground conditions.

¢ To combine the fitted demand and supply functions into a
single analytical model and apply them to a new site, it
is necessary to establish a common unit of account for
incomes and for housing services, so that fitted param-
eters are consistent with the data for the new site.
This can be done with the aid of a consumer price index,
a factor-price index, and some strong assumptions.
o The range of observations on which the demand and supply functions are estimated limits the applicability of the fitted functions to new sites, where the data may fall outside that range.

o While the experiments provide data that can be used in conjunction with untested public contribution rates for either housing-gap or housing-discount formulas, earmarking provisions must have been tested. If they are of a kind that renders certain building types ineligible, or that requires a minimum level of housing services, they must be tested in the Supply as well as the Demand Experiment, or else their effects on suppliers in those market sectors must be modeled.

If this scheme for analytical integration of data from the Demand and Supply Experiments survives general scrutiny, the designers of both experiments should keep in mind its data requirements. It does not appear to call for any drastic revision of present plans. In crude form, at least, it can be implemented and would be useful to HUD and to others concerned with housing allowances. However, we suspect that the analytical extensions of experimental findings described here will have much less influence on thinking about housing allowances than the more directly observable outcomes of the experimental programs at the sites where they are mounted.
