MEMORANDUM

5/17/48

SUBJECT: TESTS OF THE RANDOMNESS OF DIGITS
BY: Bernice Brown
COPIES TO: Evaluation Section

Introduction

In this report we shall examine the randomness of a million digits which were produced at Project RAND by a random digit generator. The basic principle underlying the design and construction of the random digit machine is that of an electronic binary counter which counts pulses from a random frequency pulse source. A report describing the machine will be forthcoming. A series of tests applied to periodic samples of digits produced by the machine indicated that a small bias (.006) favoring the odd digits might be present in the table of a million digits, ^[1]. Following a suggestion made by G. W. Brown, this table was re-randomized by a process that involved forming sums of paired digits modulo 10, ^[2]. It is the purpose of this report to present the results of an examination of the million re-randomized digits in an attempt to insure the randomness of the numbers for the user of random numbers in common types of sampling inquiries.

Procedure

Four methods of examining the million digits for randomness have been utilized. All tables and computations were accomplished by use of IBM equipment.

1. Frequency Tests

A table of aggregate frequencies was prepared with a record of the total frequency of occurrence of each of the ten digits for one million numbers in 20 samples of 50,000 digits each.

2. Examination of Chi-square Distribution

The million digits were examined in blocks of 1000 digits each. A set of 1000 summary cards was prepared; each card containing the ten observed frequencies; the computed Chi-square for these frequencies and the probability of getting χ^2 equal to or smaller than that observed. These quantities were calculated from the formulae,

$$\chi_i^2 = \frac{1}{100} \sum_{j=0}^9 (x_{ij} - 100)^2 \quad (i=1,2,\dots,1000)$$

$$P(\chi^2) = \frac{1}{\Gamma(\frac{9}{2})} \int_0^{\chi_i^2} \left(\frac{t^2}{2}\right)^{\frac{9}{2}-1} e^{-\frac{t^2}{2}} dt$$

where $x_{i,j}$ represents the observed frequency of the digit j in the i th sample of 1000 digits.

3. Poker Test

The million digits were scanned in groups of five digits each, simulating 200,000 poker hands and a record made of the number of hands which contained five differing digits, busts (symbol abcde), number of pairs (symbol aabcd), two pairs (symbol aabbc), three digits alike (symbol aaabc), full house (symbol aaabb), four digits alike (symbol aaaab) and all five digits alike (symbol aaaaa). Records of the frequencies in the seven classes of poker hands were kept for every 1000 poker hands examined. The tabulation sheets thus supplied us with 200 frequency distributions, each of which could be compared with the theoretical frequency distribution.

4. Serial Test

The serial test was applied to a sample of 50,000 digits from the table of the one million re-randomized digits. This block of digits constitutes a 5% sample from the million digit table. The object of the serial test was to see if a given digit tended to be associated with any other digit.

Results

1. Frequency Tests

The frequency of the occurrence of the ten digits in each of 20 successive samples of 50,000 is shown in Table I, together with total frequencies. For $N = 10^6$, the expected mean (m) is 10^5 with standard deviation (σ) of 300. Six of the observed frequencies are within the interval $m \pm \sigma$ and in only two cases is the deviation from expected more than 2σ . The χ^2 value for 9 degrees of freedom is 13.3 and the probability of exceeding this value is approximately 0.15.

The total number of even digits is 500,586 as against 499,414 odd digits. Under the hypothesis of equal probabilities, the deviation of 586 is not large enough to show significance. Using the t test, $t = 1.172$, $d.f = \infty$, $P = 0.24$. (Under these circumstances $t = \chi$ and the χ^2 test for 1 degree of freedom would give an equivalent result).

The frequency Chi-square for 9 degrees of freedom may be analyzed into three component parts; one degree of freedom for the comparison of odd and even digits, four degrees of freedom for variation

TABLE I
Frequencies of One Million Digits (Re-randomized).

No.	f ₀	f ₁	f ₂	f ₃	f ₄	f ₅	f ₆	f ₇	f ₈	f ₉	χ^2

20	4963	5013	5101	5084	4956	4972	5018	4971	5021	4901	6.584
Total	99802	100050	100641	100311	100094	100214	99942	99559	100107	99280	13.316
$f_{ij} - 10^5$	-198	50	641	311	94	214	-58	-441	107	-720	

between frequencies within the group of odd digits and four degrees of freedom between digits within the even number group. These components of Chi-square are as follows:

	<u>χ^2</u>	<u>d.f.</u>	<u>Probability</u>
Comparison of frequencies of odd vs. even digits.	1.37	1	0.25
Frequencies within group of odd digits.	7.90	4	0.10
Frequencies within group of even digits.	4.04	4	0.40

The result of this analysis of Chi-square into its components upholds the hypothesis that the sampling is from a population in which the digits occur with equal probabilities. There is no indication of any differentiation in the behavior of odd and even digits. An inspection of the frequencies shows that the digit which appeared most frequently (two) was associated with a probability of 0.1006 while the least frequent digit (nine) had a probability of 0.0993.

The computed sample χ^2 values are shown in the column on the right for samples of 50,000 digits. Each of these Chi-square values is associated with 9 degrees of freedom. The distribution of the observed Chi-squares is in line with expectation. Two of the 20 values give probabilities of exceeding the observed χ^2 value of more than 0.90; two give probabilities of less than 0.10. In 12 samples the χ^2 values are small enough to give probabilities of more than 0.50; 8 samples show probabilities of less than 0.50. For $n = 50,000$ the expected mean is 5,000 with standard deviation of $30\sqrt{5}$ (67.08). Of the 200 recorded frequencies, 129 or 64.5% are within one standard

deviation of the mean. There are eight cases or 4% in which the deviation of observed frequency from expected frequency exceeds 2σ .

2. Examination of Chi-square Distribution

In Figure 1, the cumulative distribution function of χ^2 has been plotted against the χ^2 values. The χ^2 values were arranged in 50 class intervals with probability in each class approximating 2%*. It will be observed that the theoretical and actual distributions are in agreement except for a slight disparity in the range of values from 9.0 to 10.5. A χ^2 test was applied to determine whether the observed frequencies in the 50 classes differed significantly from the theoretical values. A χ^2 of 54.6 was obtained. There seems to be nothing unusual about getting a χ^2 as high as 54.6. Since it is associated with 49 degrees of freedom, the resulting probability is about 0.55 using Fisher's [4] approximation.

3. Poker Test

Two hundred Chi-squares were calculated which measured the dispersion between expected and observed frequencies in each sample of 1000 poker hands. The expected distribution of frequencies for samples of 1000 are busts 302.4, pairs 504, two pairs 108, threes 72, full house 9, fours 4.5 and fives 0.1. The expected frequencies in the last two classes were small, hence they were combined in one group.

* Wald and Mann [3] have shown that an optimum way of determining the number of class intervals k in which the range of the sample χ^2 's is to be divided, is given by $k = \frac{4\sqrt{2(N-1)}^2}{C^2}$ where C is the value of the normal deviate at the level of significance desired and N is total frequency.

CUMULATIVE DISTRIBUTION FUNCTION OF X^2 VALUES AND THEORETICAL DISTRIBUTION FOR 9 DEGREES OF FREEDOM

DATA OBTAINED FROM 1000 SAMPLES OF 1000 DIGITS EACH

FIG. 1

The observed distribution of χ^2 is compared with the theoretical distribution for five d.f. in Table II.

Table II

Frequency Distributions of Chi-square Values

<u>Probability</u>	<u>Values of χ^2</u>	<u>Expected Freq.</u>	<u>Observed Freq.</u>
P > .90	0 - 1.60	20	22
.90 > P > .80	1.61 - 2.35	20	19
.80 > P > .70	2.36 - 3.00	20	22
.70 > P > .60	3.01 - 3.70	20	19
.60 > P > .50	3.71 - 4.35	20	20
.50 > P > .40	4.36 - 5.20	20	29
.40 > P > .30	5.21 - 6.10	20	22
.30 > P > .20	6.11 - 7.30	20	15
.20 > P > .10	7.31 - 9.20	20	15
P < .10	9.21 or more	<u>20</u>	<u>17</u>
		200	200

$\chi^2 = 7.7$ for 9 d.f. P = 0.55

The agreement of the two distributions indicates that the Chi-squares obtained experimentally from the table of random digits are compatible with the tabular χ^2 values for 5 degrees of freedom.

The frequencies obtained from the poker test were combined and the results of the aggregate of 200,000 poker hands are shown in Table III.

TABLE III

Poker Test on Million Digits (200,000 Poker Hands)

<u>Classes</u>	<u>Expected Frequency</u>	<u>Observed Frequency</u>
Busts (abcde)	60,480	60,479
Pairs (aabcd)	100,800	100,570
Two pairs (aabbc)	21,600	21,572
Threes (aaabc)	14,400	14,659
Full house (aaabb)	1,800	1,788
Fours (aaaab)	900	914
Fives (aaaaa)	20	18
	<u>200,000</u>	<u>200,000</u>

$\chi^2 = 5.5$ for 5 d.f.

P = 0.35

The agreement of observed and expected frequencies in Table III is good. The only sizable difference is in the class of threes (aaabc). The difference, 259 is 2.25 times the theoretical value of the standard deviation, 115.6 for this class. Considered by itself, a deviation of this magnitude would ordinarily occur one time in 40. The value of χ^2 for all the frequencies of 5.5 with 5 degrees of freedom is not excessive.

The frequencies of Table III may be broken down into ten equal groups, each representing 20,000 poker hands (100,000 digits) in order to look at the consistency of the behavior of the poker hands. The theoretical mean and standard deviation for each class was calculated under the assumption of equal probability of occurrence of each digit. The comparison of actual and theoretical values of mean and standard deviation is shown in Table IV.

Table IV

Mean and Standard Deviation of Frequencies
in 7 Classes of Poker Hands

<u>Classes</u>	<u>Theoretical Mean</u>	<u>Actual Mean</u>	<u>Theoretical Std. Dev.</u>	<u>Actual Std. Dev.</u>
abcbe	6048	6047.9	64.9	60.3
aabcd	10080	10057.0	70.7	78.4
aabbc	2160	2157.2	43.9	45.8
aaabc	1440	1465.9	36.9	26.6
aaabb	180	178.8	13.4	8.9
aaaab	90	91.4	9.5	11.5
aaaaa	2	1.8	1.4	1.9

With the possible exception of the class of poker hand in which three of a kind appeared (aaabc), the actual means and standard deviations are satisfactory estimates of the theoretical values. In the class referred to above, the mean was overestimated and the standard deviation was underestimated.

5/17/48

4. Serial Test

The frequency of the occurrence of all possible pairs of digits is given in Table V.

TABLE V
Serial Test

		Frequency of Occurrence of 1 st Digit										
		0	1	2	3	4	5	6	7	8	9	Total
Frequency of Occurrence of 2 nd Digit	0	508	510	451	500	513	475	494	508	463	501	4923
	1	456	514	523	472	561	490	486	512	503	496	5013
	2	509	474	493	476	481	527	491	454	475	536	4916
	3	507	514	484	466	485	507	483	498	514	493	4951
	4	502	504	502	513	526	493	525	550	520	474	5109
	5	489	481	466	478	513	481	504	533	544	504	4993
	6	471	496	514	540	485	489	530	516	514	500	5055
	7	504	486	506	513	510	512	539	504	491	515	5080
	8	488	507	493	530	524	465	513	485	520	461	4986
	9	489	527	484	463	511	554	490	520	442	494	4974
Total	4923	5013	4916	4951	5109	4993	5055	5080	4986	4974	50000	

This table was formed by entering a pair of digits $x_i x_j$ in the i th column and the j th row; e.g., if a sequence of four digits is 6203, a frequency is recorded in the 6th column, 2nd row - one in 2nd column, 0 row and one in 0 column, 3rd row. In order to complete the circuit and make the 50,000 digits give exactly 50,000 pairs, the last digit was combined with the first to form a pair.

Let us consider, first of all, the probability of getting the sample from a population in which the digits were equally likely to occur. The frequency χ^2 as calculated from the row or column totals is 7.56. This is based on 9 degrees of freedom. The probability of getting a Chi-square equal to or greater than 7.56 is about 3 in 5. This sample of 50,000 does not show unusual divergence. The frequencies obtained here would be encountered often in sampling.

Three Chi-square tests were applied to the data in Table V. The first tested the hypothesis that the array was a random sample from a population in which one pair of digits was as likely to occur as another. The expected frequency in each cell was 500. (Kendall and Smith [5], [6] apply this test to Tippett's published table of random numbers). The χ^2 value for 90 degrees of freedom was 107.8. The probability of getting a $\chi^2 \geq 107.8$ for 90 degrees of freedom is about 0.10. There is no evidence that the sample was not drawn from the population specified.

The second tested the hypothesis that any given digit was as likely to be followed by one digit as by another. The method of computing the expected number in each cell is based on the actual frequency: e.g. since the actual frequency of zeros was 4923, the expected value in each cell in the 1st column of Table V was 492.3. A similar computation was made for the other nine frequencies. The χ^2 value was 98.9. The probability of getting a $\chi^2 \geq 98.9$ with 90 d.f. is 0.25. The deviations from expected values are not large enough to discredit the hypothesis.

5/17/48

The third test was used to check the hypothesis that any given digit is as likely to be preceded by one digit as by another. If the preceding digit is equally likely to be 0,1,2,...9, the expected value in each cell of the first row was 492.3, in the 2nd row 501.3 etc. The value of χ^2 was 100.4. The probability of getting a $\chi^2 \geq 100.4$ is approximately 0.20. The evidence presented by the sample is compatible with the stated hypothesis.

Conclusion

The examination of the million re-randomized digits has shown no discrepancies other than the expected sampling fluctuations. The frequency test indicated that all the digits occurred approximately an equal number of times. The distribution of sample Chi-square values agreed closely with the theoretical distribution. When the digits were examined in groups of five each, the observed frequencies compared favorably with the expected frequencies. The serial test revealed no tendency for any particular pair of digits to be associated together. None of the tests contradict the assumption of randomness in the series of one million re-randomized digits.
